THURSDAY, MARCH 2, 1911.

RESEARCHES ON RADIOACTIVITY.

Traité de Radioactivité. By Prof. Mme. P. Curie. Tome i., pp. xiii+426. Tome ii., pp. 548. (Paris: Gauthier-Villars, 1910.) Price, 2 vols., 30 francs.

NO more effective illustration of the rapidity of advance of accurate knowledge of radioactivity can be taken than a comparison of the two books published on the subject by Mme. Curie, at an interval of seven years. The first, published as a thesis for the doctorate of science in 1903, was a small volume of 142 pages, and gave an account, not only of her own work, but of most of the important facts known in radio-activity at that time. The second, published at the close of 1910, consists of two volumes, containing in all nearly a thousand closely-written pages, and giving an orderly and systematic account of the large mass of data that has been accumulated in the interval. The remarkable rapidity of advance of this new branch of science largely results from two factors—the discovery and isolation of radium by Prof. and Mme. Curie, and the development of the transformation theory in 1903.

The discovery of radium gave an opportunity to the investigator of obtaining intensely radio-active material, in which the typical radio-active effects are shown on a very marked scale. The remarkable properties of radium attracted the attention of the scientific world, and gave a great impetus to the study of radio-activity. On the other hand, the transformation theory has proved an invaluable guide to the investigator in disentangling the apparently complicated processes occurring in radio-active matter. It offers a rational explanation of practically all the experimental facts that have been discovered, and has been instrumental in bringing to light a number of unsuspected relations of great importance.

This work represents, with additions, the course of lectures on radio-activity given by Mme. Curie in the Sorbonne. The first chapter is devoted to an account of the conduction of electricity through gases, and the second to a description of the methods employed in radio-active measurements. The latter contains a somewhat detailed account of the theory of the electrometer and of the quartz piezo-electrique devised by J. and P. Curie. Chapters iii. and iv. include an account of the general radio-active properties of uranium and thorium, and of radio-active minerals, and a very complete account of the methods of isolation of radium and polonium and other radio-active materials. This chapter will be read with especial interest, as it is largely an account of the author's well-known discoveries. The next three chapters deal with the radio-active properties of the emanations, and of the active deposits which are derived from them. A very full description is given of the methods employed in determining the molecular weight of the emanation by diffusion methods, and also a clear account of recent work upon the purification of the radium emanation, the determination of its volume, and of its physical and chemical properties. In chapter viii., after a review of the various theories proposed, the transformation theory is adopted, and the mathematical theory of successive transformations is given. Then follows a long chapter of more than 200 pages, giving a systematic account of the nature of the radiations from radio-active bodies, followed by a discussion of the general physical and chemical effects shown by the radiations, including the production of helium from radio-active matter, and an account of the experiments which have been made by Ramsay and others to test whether the radiations from active matter are able to transform inactive elements. After a discussion of the various experiments, Mme. Curie sums up as follows:—

> "En résumé, on peut considérer qu'il n'y a pas encore actuellement de raisons suffisantes pour admettre que la formation de certains éléments puisse être provoquée à volonté en présence de corps radioactifs. La production d'hélium reste acquise; mais elle est reliée à une propriété essentielle des éléments radioactifs et n'est pas influencée par l'intervention de l'expérimentateur."

Chapter xi. gives an account of the methods of measurement of heat emission of the radio-active substances, while the next four chapters deal with suc-

cessive transformations occurring in uranium, thorium, radium, and actinium, followed by an account of the origin of radium and the discovery of ionium, and the discussion of the general connection between the radio-active series. The last chapter is devoted to a consideration of the radio-activity of the earth and atmosphere.

An excellent portrait of Pierre Curie is given in the frontispiece. Several interesting reproductions are included at the end of the volume in illustration of the photographic effects of the various radiations. Carefully prepared tables are included in the text, giving the important radio-active constants, while a table of exponential values is added for convenience in calculating the decay and growth of the radium emanation.

In these two volumes, written in a clear and interesting manner, Mme. Curie gives a full and complete account of practically all the work of importance that has been done in radio-activity. It is a storehouse of accurate information. The author has shown judgment in the selection of data and in discussion of points at issue. The chemical methods of separation of radio-active products are in most cases briefly given, while a detailed account is included of the methods of separation of radium and of polonium. This is excellent so far as it goes, but it does not fill the pressing need at the present time of a practical book on the methods of separation and purification of the numerous radio-active products. Such an account should prove of the greatest value both to chemists and physicists, for it is becoming more and more important in many lines of work that the investigator should be able to separate and concentrate the various radio-active products. Such an account can only be written by an expert both on the physical and chemical side who has himself worked over the subject, for more than a compilation of chemical methods is required.

It is always a difficult matter in a work of this character, which treats of a rapidly growing subject, to give full credit to pioneer discoveries, and at the same time to do justice to later work of a more detailed and accurate character. Mme. Curie has, to a large extent, overcome this difficulty by giving a fairly detailed account of the original experiments, and a more condensed statement of subsequent work.

There is very little to criticise and much to admire in this notable work. It is remarkable what little difference of opinion exists among radio-active workers on the interpretation of the main phenomena. This is no doubt mainly a result of the general adoption of the theory of atomic disintegration, for on this theory only one explanation is in most cases admissible. While there is a general agreement on the fundamental points, there is naturally room for wide difference of opinion on matters still under investigation. This is well illustrated by the conflicting views that are at present held on the difficult question of the nature of the emission and of the absorption of the β and γ rays by active matter. The advocacy of rival views on such questions is in many cases a great advantage, for it gives an incentive to a more accurate and complete investigation of the problem under consideration.

While the reviewer finds that he is in substantial agreement with all the main conclusions of Mme. Curie, there are a few minor points to which attention may be directed. Mme. Curie includes radio-uranium as a possible product of uranium, although a note of interrogation is attached. She certainly makes a better case for its existence than is given in the original publication; but until more definite information is forthcoming it does not appear desirable to include it in the uranium series. The products radium E_1 and radium E_2 are retained, although later work of Antonoff has indicated conclusively that only one product of period about five days which emits β rays can be present. The discovery of ionium is credited to Rutherford and Boltwood; it should be Boltwood. The original suggestion that lead is a final product of the transformation of radium is attributed to Rutherford. It should be Boltwood. The term "radio-active induite" is used widely throughout the work. While the use of this expression is historically justified, it is a misnomer, especially when used in reference to radio-active *matter* deposited from the emanation. The term "active deposit," which has come into general use, is a very convenient substitute, and it is desirable that the original names, "induced," or "excited," activity, should disappear from the literature.

The lack of a name- or subject-index is a serious drawback to the usefulness of this treatise. The references to literature are incomplete, the name of the journal and the year of publication alone being given.

As an account of a youthful branch of science, the present treatise may appear somewhat lengthy; but it must not be forgotten that the subject of radio-activity now covers a very wide field of work. It has to treat, not only of the nature of remarkable types of radiation which are emitted, but also of the origin and physical and chemical properties of more than a score of new transition elements. In addition, it has to deal with the distribution of radio-active matter in the earth and atmosphere, and its bearing on atmospheric electricity and on problems connected with geology. Unless this treatise is to become unwieldy in size, it will be necessary in future editions, where much new work has to be included, to adopt a policy of more rigid selection and compression of the experimental data to be discussed. No doubt as our knowledge of the various questions becomes more definite, it will not be so difficult as at present to give a complete review of theory and experiment within reasonable limits of space.

The present work will be read with the greatest interest by all workers in radio-activity as an authoritative account of the subject from one who has made notable contributions to its history. The book is essentially written for the investigator rather than for the ordinary student, and will be of the greatest service to the former as a complete and accurate review of all important publications on the subject. Every reader will recognise the great labour and patience involved in writing a complete treatise on such a rapidly growing subject, and Mme. Curie is to be congratulated on the success of her efforts.

This treatise is a noteworthy contribution to the

literature of this new and fascinating field of scientific inquiry, and redounds to the credit of Mme. Curie, and to the nation which has taken such a fundamental and prominent part in the development of radioactivity.

E. R.

DYNAMO-ELECTRIC MACHINERY.

The Dynamo: Its Theory, Design, and Manufacture. By C. C. Hawkins and F. Wallis. Fifth edition. Re-written, revised, and enlarged. Vol i., pp. x+542. Vol. ii., pp. viii+543–1134. (London: Whittaker and Co., 1909.) Price 21s. net, two vols.

THE increase in the size of Messrs. Hawkins and Wallis's book is a good indication of the progress that has taken place in the practical development of the dynamo. Little or no addition has been made in the interval to the fundamental theory of direct-current and alternating machines; an immense advance has been made in the mastery of the thousand and one details of selection of materials and methods of construction of machines for different purposes.

Vol. i. is mainly theoretical, and contains statements regarding the physical facts and theories on which electric generators and motors are based. The treatment of the magnetic circuit, of self-induction and alternating currents, the classification of dynamos, the magnetic properties of iron, and so forth, strike one as exceedingly satisfactory. In general there is a clear perception of what constitutes a proof of a theorem and what a mere illustration or representation of results. It is possible to frame graphical proofs of theorems of electromagnetism, as of dynamical theorems regarding stresses in the members of a girder, and it is a good thing to do so; but many so-called graphical "proofs" are mere illustrations of results which have been so far only satisfactorily established by analysis. The graphical representation displays to the eye connections of things set forth in equations, and so far as possible this should be done in all departments of mathematical physics; but the student should not be led to imagine that he has got to the root of the matter, when he realises that $\sqrt{R^2+n^2L^2}$ is the length of the hypotenuse of a right-angled triangle, the lengths of the sides of which are R and nL. As it seems to us, Messrs. Hawkins and Wallis have given a very happily blended analytical and geometrical discussion.

The analogy of inductance and capacity to inertia and the slackness of a buffer spring, of the electrokinetic energy $\frac{1}{2}Li^2$ to the kinetic energy of a carriage, and the analogy of the dissipation of this kinetic energy, when the carriage is brought to rest by collision with the buffers, to the break of a circuit containing a condenser, gives a clearer idea of what happens than general statements, and we should have liked to see some such practical "engineering" illustrations in the chapter on self-induction.

Then it is a little difficult to distinguish, as the authors seem to do on p. 69, between "the current itself," and the magnetic field which it produces. Is it not all one phenomenon? One may try to distinguish between the current—the motion of electrons (or, as someone has illuminatingly called them, the essential singularities that are at the root of all electrical action)—and the magnetic field, but is it possible to do so really? One cannot have a vortex filament in an infinite fluid without the irrotational flow which constitutes its field. It may be said that by twisting the outward and inward wires of a circuit together or by putting one inside the other, a field can be avoided; but the assertion is only true for space external to the conductors. A field can only be avoided altogether by making the going and returning conductors absolutely coincident, in which case there is no current.

The molecular theory of magnetism may possibly require modification in view of still more modern theories of the electrical constitution of matter; but it has done much service in clarifying the ideas of students of magnetism, and it still substantially fits the facts. How often did one find in elementary books the higgledy-piggledy arrangement of molecular magnets pictured, to explain to the reader the constitution of a body in the neutral state? It never seemed to occur to the writers that these magnetic molecules must act on one another, and that the perfectly fortuitous arrangement was unlikely to have been set up, or to remain if it were. The closed chains were in the minds of many; the exhibition of Ewing's model made clear how these closed chains led to the observed magnetisation curves.

During the last year or two much further work on magnetic induction in iron and alloys has been done, and on the influence of treatment of different kinds: it will be for the dynamo builder and user to examine whether any part of the work is likely to be of use to them. But no doubt for a long time the knowledge that has been accumulated of the constants of steel of different kinds, in stampings of different thicknesses, will be sufficient for their needs.

Chapters xiv. and xv. of the first volume, on "Field-Magnets" and "The Ampere-Turns of the Field" respectively, are exceedingly instructive and interesting, and are, of course, of great importance, for the proper design of a dynamo or motor for a given specified purpose depends entirely on a due appreciation of the principles laid down in every sound discussion of this subject.

In vol. ii., after a discussion of armature reaction which seems adequate, a long chapter (110 pages) is given on "Commutation and Sparking at the Brushes." This important subject is very fully dealt with, apparently with a thorough appreciation of all that has been done on the subject of commutation and the factors on which sparking at the brushes depends, and also of the quantitative laws of the matter so far as these have been theoretically and empirically compiled.

Chapters follow on the "Design of Continuous-Current Dynamos and Alternators," and these are based on a full description of all the various forms of armatures and field-magnets in use in the various types.

The book, if a little heavy (in avoirdupois), is beautifully printed and magnificently illustrated with 594 pictures, diagrams, and cuts of different sorts, and reflects credit on authors and publishers alike.

A. G.

RÖMER'S ADVERSARIA.

Ole Römer's Adversaria, med Understöttelse af Carlsbergfondet udgivne af det Kgl. Danske Videnskabernes Selskab. By Thyra Eibe and Kirstine Meyer. Pp. v+271. (Köbenhavn: Bianco Lunos Bogtrykkeri, 1910.)

AMONG astronomers Ole Römer (1644–1710) occupies a peculiar position. He was held in high repute among contemporary men of science, as may be seen from the fact that Newton and he were the first astronomers to be enrolled among the eight foreign associates of the Paris Academy of Sciences, and were elected on the same day. To posterity he is known as the discoverer of the gradual propagation of light, and as the man who introduced the use of (if he did not invent) the transit instrument and the transit circle. And yet his published writings only fill a few pages, and the observations he made with instruments far superior in design to those of his time, were not printed, and nearly all of them perished not long after his death. There is, therefore, every reason to welcome the publication of his common-place book, which has been brought out just two hundred years after his death.

Like every other book of its kind, the present book of Adversaria deals in a scrappy way with a great variety of subjects, and it shows what chiefly occupied Römer's mind, especially during the last ten years of his life. We see him as a practical astronomer, as a physicist, and as a man who had for many years served his country well by reorganising the system of weights and measures, getting the Gregorian calendar introduced, and preparing a uniform system of land taxation. But though these various occupations, which gradually came to fill most of his time to the great loss of science, are now and then alluded to in the present volume, they do not fill many pages in it. It looks as if Römer was in the habit of taking refuge in his commonplace book when he wanted to refresh his mind after his hard work as Burgomaster and Chief of Police of Copenhagen. To give a full account of the contents of his notes is not possible in a limited space: we can only give the reader some idea of the kind of subjects dealt with. An important section on thermometers, dating from 1702, has already been described in NATURE, (vol. lxxxii., p. 296). Römer appears to have been the first to construct thermometers with two fixed points, marking the temperatures of melting snow and of boiling water, and he was the inventor of the scale known as Fahrenheit's.

Turning to astronomical matters, we find Römer to have been a follower of Descartes in his views on the construction of the universe, though his own discovery about light did not exactly harmonise with Cartesian ideas. He inquires at what distance a planet or satellite would have to be from the central body according to the third law of Kepler in order that its period of revolution may equal the period of rotation of the central body. In the case of a planet he finds the distance equal to 37 semidiameters of the sun, in the case of a satellite of the earth $6\frac{1}{2}$, and for a satellite of Jupiter 2 semidiameters of the respective planet. This, he thinks, may be made to agree with the vortex theory by assuming that radiation from the central body impedes the rotation of the ether, and this radiation, being naturally much more powerful from the sun, causes its influence to be felt at a much greater distance than that at which the radiation of a planet is perceptible. He shows himself interested in solar phenomena by calculating the apparent position of the sun's axis, and of the path of sun-spots for every $7\frac{1}{2}°$ of longitude of the sun, having first determined the inclination of the sun's equator and the place of the node with fair accuracy from his own and La Hire's observations. It will be remembered that the sun's equator was in those days often used as a fundamental plane or Via Regia of the solar system. He calculates the transit of Mercury of May, 1707, from Kepler's elements and observations by Hevelius of the transit of May, 1661. He calculates the solar eclipse of September 13, 1708, for Copenhagen, and Holum in Iceland, and gives rules for the prediction and graphic representation of an eclipse. The transit instrument in the prime vertical, of which he had introduced the use, is employed for the determination of the vernal equinox of 1702, and he examines the consequences of errors of observation in the transit, and shows how to determine the error of collimation by reversing the instrument.

The above examples, which could easily be multiplied, will show that the two ladies who have edited this book have done good work by bringing it to light. There is a useful index and an excellent table of contents, and every care seems to have been taken to produce an accurate edition of the old manuscript. The few Danish words or sentences occurring here and there might have been translated in foot-notes for the convenience of readers not acquainted with that language.

J. L. E. D.

GALL-FLIES AND OTHERS.

Das Tierreich. Eine Zusammenstellung und Kennzeichnung der rezenten Tierformen. Edited by F. E. Schulze. 24 Lieferung. Hymenoptera. Cynipidæ. By Prof. K. W. von Dalla Torre and Prof. J. J. Kieffer. Pp. xxxv+891. (Berlin: R. Friedlander and Son, 1910.) Price 56 marks.

THIS work forms a worthy volume of the series of zoological works published under the general title of "Das Tierreich," by Messrs. R. Friedlander and Son, of Berlin. It is an extension of the two volumes by Dr. Kieffer in André's "Species des Hyménoptères d'Europe et de l'Algérie." Dealing as it does with the Cynipidæ of the whole world, and containing descriptions of all the known genera and species, the book is indispensable to students of the Cynipidæ. Theodore Hartig was the pioneer of the scientific study of the group. He placed the classification on a proper basis, and was the first to point out the threefold habits of the species—gall-makers, inquilines, and parasites. After him came Giraud, Schenk, and, above all, G. L. Mayr, who made the identification of the galls easy by the publication of beautifully illustrated works on the species of Central Europe, as well as a monograph on the guest-flies (Synergi).

Then came the epoch-making discovery by Dr. Adler of the existence of alternations of generation—that a spring bisexual form was followed by an autumnal unisexual one, the two forms having totally different galls.

The volume commences with a list of the authors who have published separate works, and of the titles of the journals and transactions of scientific societies in which papers have appeared, the total number being 252, beginning with Malpighi in 1675. The titles of papers in magazines and transactions are not given. If they had we should have had the names of T. A. Marshall, E. A. Fitch, Prof. J. W. H. Trail, and other workers at British cecidology, besides the seven British authors given in the catalogue. We notice that while the list contains the French translation of Adler's papers, no mention is made of the English one by Mr. Standen. Next we have a "systematic index" of the genera and species, followed by the descriptions of the subfamilies, genera, and species, the whole concluding with a good index of the genera and species, but not of the plants, and a "Nomenclator generum et sub-generum." There are no figures of entire insects, but there are some illustrating the structure in the introduction, while there are 398 wood-cut illustrations of galls.

The authors divide the family into ten subfamilies and 126 genera, besides two doubtful ones; describe fully 1281 species, as well as 102 subspecies; in addition there are 212 species which have been too briefly described for recognition, and of which the original descriptions are reprinted. Some changes in generic nomenclature are made. Allotria, West., and Xystus, Htg., its synonym, are suppressed, both being preoccupied. In place of them Dr. Kieffer adopts Charips, a MS. name of Haliday, first used by Marshall. The name of Diplolepis is revived after long disuse, it replacing Dryophanta. On the other hand Ashmead considers it to be the same as Diastrophus. The system of subgeneric names and trinomials for the species with well-marked varieties is adopted. Thus we have Eucœla and Cothonaspis, both with nine subgenera, the latter being genera with Foerster and Ashmead. This method, in some cases, leads to a species having four names, *e.g.* we have *Eucoila Psichacra Marshalli Marshalli* for the typical form of Cameron's species, and *Eucoila Psichacra Marshalli rufo-notata* for the variety.

An interesting fact in the biology of the parasitic Cynipidæ is that some species are found in ants' nests. Long ago Westwood bred *Charips victrix* from the rose aphis, and as many other species of the same genus have also been bred from plant-lice, it might fairly be concluded that the genus was a beneficial one. There is now, however, reason to believe that Charips is a hyperparasite, destroying, not the aphis, but the beneficial Braconid which preys on it. If that is so the species must be looked upon as injurious. The present writer has seen *Charips victrix* ovipositing in plant-lice killed by Aphidius, which pupates in the lice, the bodies of which become dried, inflated, and are attached to the leaf by the parasites. *Cothonaspis zig-zag* is another injurious hyperparasite, it destroying *Phora aeletiae*, the parasite of the injurious cutworm of the cotton. Among the habitats of the Parasitica is the sea-shore, where two British semiapterous species are found at high-water among seaweed.

It is curious how the Cynipidæ form their galls on certain plants more than on others. The oak in Europe and in North America is the predominant food-plant. In Europe *Quercus pedunculata* harbours ninety-nine species, *Q. pubescens* seventy-nine, and *Q. sessiliflora* ninety-six. After the oak come the Rosaceæ—Rosa, Rubus, Potentilla. The poppy has two species in the fruit and one in the stem. It is remarkable that the willows, on which there are so many dipterous and saw-fly galls, have not one species of Cynipidæ attached to them.

As regards the distribution, Dr. Kieffer gives some curious examples of the unequal manner in which some genera are distributed in Europe and North America. Callirhytis has four species in Europe, in America fifty-two. Rhodites has twelve Palæarctic and seventeen Nearctic, while Lytorhodites is exclusively Nearctic, as is also Amblybolyps with twenty-four species. A few species are found in Europe and North America, *e.g.* our "begeguar" and *Aulax latreillei* on *Glechoma hederacea* as in Europe, while *Rhodites eglanteriae* is recorded from the West Indies. Solanum should be deleted from the list of food-plants, it being now known that the galls of *Tribalia batatorum* came from the rose and not from the potato. Ashmead is no doubt correct in considering Tribalia to be identical with Lytorhodites.

There are one or two points in the work which concern our British species—Aulax, Hartig, is split up into two—Aulax (Kieffer retains the old, incorrect spelling, Aylax) with *latreillei*, Kief. (*glechomae* of Cameron's monograph), *hypochoeridis*, *papaveris*, *minor*, *scabiosae*, and *Fitchi*; and Aulacidea with *hieracii* and *graminis*. We doubt if *Cynips kollari*, our common "marble gall" fly, is dimorphic, and that *Andricus circulans* (a Turkey-oak species found in Britain only in Kew Gardens) is its sexual form. Our own experiments appear to show that it is agamic, while, if *A. circulans* were its sexual form, it surely should be equally common and as widely distributed.

In conclusion, we have to congratulate cecidologists on the appearance of this admirable and thorough work, which will be as useful to the beginner as to the advanced student in all parts of the world.

P. C.

THE CRYSTALLISATION MICROSCOPE.

Das Kristallisationsmikroskop und die damit gemachten entdeckungen insbesondere die der flüssigen Kristalle. By Prof. O. Lehmann. Pp. iv+112. (Braunschweig: F. Vieweg and Son, 1910.) Price 3 marks.

PROF. LEHMANN is gifted with the pen of a ready writer, and has in recent years poured forth such a voluminous stream of papers and books dealing with the subject of mobile crystals in its many aspects that considerable overlapping and repetition necessarily exists in them. Such criticism may be levied also against the present little book, which first

saw light in the pages of a *Festschrift,* issued by the Technische Hochschule in Carlsruhe, to commemorate the fifty-third birthday of the Grand Duke of Baden. It does, however, contain detailed descriptions of the latest forms of the microscope which have not appeared in print before, and would, moreover, be welcomed for the sake of the interesting historical account of Prof. Lehmann's researches, which spares the student of the subject the difficulty and trouble of hunting up a series of papers published at various dates and in various periodicals.

Nearly forty years have elapsed since Prof. Lehmann, while still a student, first devised a form of microscope by means of which substances could be observed at higher than ordinary room temperature, and the phenomenon of crystallisation watched in actual operation. The results of the research thereby rendered possible were, as is well known, unexpected and startling, and the meaning and even the reality of the observations were for long the subject of considerable discussion and dispute. Other workers have, however, in recent years entered the field, who on the whole have confirmed the accuracy of Prof. Lehmann's observations, and there can be no doubt but that the old ideas regarding crystals and crystallisation needed extensive modification. The investigations are discussed in chronological order in the present book, but since we noticed them less than two years ago (NATURE, 1909, vol. lxxix, p. 286), we shall not recur to them here. With each step some improvement in the instrument or some additional facility suggested itself until it reached the most recent form, which is provided with water jackets, powerful heating arrangement, means for reading the temperature, and a camera, and even a kinematograph, for giving a faithful record of the phenomena. The descriptions of the different forms are elucidated by excellent illustrations.

The last chapter of the book might with advantage have been omitted. Discussions of one's claim to priority of discovery, and the proper appraisement of one's work rarely serve a useful purpose, and are to be deprecated.

HEAT-ENGINES.

The Steam-Engine and other Heat-Engines. By Prof. J. A. Ewing, C.B., F.R.S. Third edition, revised and enlarged. Pp. xvii+604. (Cambridge: University Press, 1910.) Price 15*s.*

IN this, the third edition, Dr. Ewing has thoroughly revised his well-known text-book, and to some extent he has rewritten certain chapters; for example, the chapter on steam turbines is new, and the greater part of that devoted to gas and oil engines. The most important departure, however, is that in dealing with the properties of steam the author has accepted the characteristic equation of Callendar along with the steam tables derived from it by Mollier. The old steam tables were based chiefly on Regnault's well-known experiments, and it has been recognised that they involve inconsistencies and errors. Prof. Callendar, whose first paper on the subject was published in 1900, has devised a method of treatment which is free from inconsistencies, and gives, when expressed in the form of tables, results which agree with all the most recent experiments, at any rate, between the temperatures of 0° C. and 200° C. Possibly Callendar's equation will not give such a close approximation to experimental results for pressures lying beyond the upper of these two limits of temperature. In the form of an appendix, Dr. Ewing has added a brief account of Callendar's characteristic equation, and of Mollier's readjustment of the constants. Dr. Ewing has also decided to adopt the Centigrade scale throughout the whole of his book.

In chapter v., which is devoted to entropy, the author describes Dr. Mollier's graphic methods of representing the properties of steam. By the aid of these diagrams the engineer has placed at his disposal a simple method of solving the problem of determining the state of steam which is expanded adiabatically from any initial condition whether superheated or not, and of determining the greatest theoretical output obtainable from steam when the initial condition and the lower limit of temperature are assigned.

Chapter viii., on steam turbines, is an entirely new chapter, and will be found of great assistance by all engineers who are interested in the design and working of the steam turbine. The whole subject of the design of the steam turbine is fully discussed both from the theoretical and from the practical side.

The last chapter is a new one on gas and oil engines. The efficiency of the ideal cycle is worked out on the assumption of constant specific heat, and the author then discusses the problem of the variation of specific heat with temperature, or in other words, the relation between the internal energy of the gas and its temperature, and discusses the effect of this variation upon the efficiency of the ideal engine working on the ordinary gas engine cycle.

In its present form Dr. Ewing's book will undoubtedly be the text-book most frequently consulted by all engineers who have to deal with steam and other forms of heat engines. T. H. B.

GEOLOGICAL NATURE-STUDY.

The Earth and its Story. By Dr. A. R. Dwerryhouse. Pp. 364. (London: C. H. Kelly, n.d.) Price 5*s.* net.

THIS book has the same title, and covers the same ground, as one issued by Prof. A. Heilprin in 1896. What Heilprin did for young American readers, Dr. Dwerryhouse does, with even greater lucidity of expression, for beginners and unprofessional naturalists in the British Isles. His book is sent out by the publishers in good clear type, and is illustrated by photographs and maps printed in a brown tint on separate sheets of thick art paper. In this respect it has an advantage over all the elementary geological text-books that we know. Moreover, it is by no means a simple text-book. It is the work of a field-observer, who wishes to bring the results obtained by geologists home to any intelligent reader. Even fossil specimens are photographed, which gives them, for the author's purpose, a desirable air of reality, though the process will find less favour with

the student of generic forms. A coloured geological map of the British Isles is also included.

We have mentioned the illustrations at the outset, since the greater number are the work of the author, and he depends much on them in the physiographic portion of the book. Those of glacial phenomena seem especially excellent. May we, however, mildly protest once more at the translation of *roches moutonnées* as "sheep-back rocks" on p. 103?

The use of parts of British Ordnance maps to illustrate geographical features is in pleasant keeping with what has been done in recent text-books in America. But we venture to question whether a book of this kind should deal with geological history by means of a summary of stratigraphy as known to us in the British Isles. Would it not seem better to widen the view of the beginner by letting him know something of the great features of life-progress on the earth? The unconformities mentioned on p. 218 have no importance, except for the specialist in western Europe; nor are the names Lewisian and Torridonian at all comparable in value with those of the other systems classified in the table, which relate nowadays to no one special country. The real interest of the Carboniferous flora is not conveyed by the statements on p. 269; nor is the development of flowering plants fairly represented on p. 311, in view of discoveries outside our islands.

This introspective point of view, which has been impressed on us for fifty years by university curricula, forces the general reader to meet such things as Coniston Limestone, Blae Wyke Beds, Kimeridge Clay, and Lower London Tertiaries, and leaves him ignorant of the Permo-carboniferous ice-age, and of the immensely interesting development of life-forms and existing land-areas throughout Cainozoic times.

Dr. Dwerryhouse, however, deals excellently with the Pleistocene ice-age, taking here a bold wide survey. As minor criticisms, we do not like the term "Ammonoid" on p. 293, as applied only to forms intermediate between Nautiloids and "the Ammonites." Something seems omitted in the account of the origin of columnar structure on p. 317; the "forces acting at right angles to *ab* and towards 1 and towards 2" are just as "equal and opposite" as those differentiated from them by these terms. The whole point seems to lie in their directions.

It will be seen that this attractive book admirably fulfils its purpose. Any limitations in the last few pages cannot for a moment be ascribed to narrowness of outlook in the author. G. A. J. C.

OUR BOOK SHELF.

British Weights and Measures. As Described in the Laws of England from Anglo-Saxon Times. By Col. Sir C. M. Watson, K.C.M.G., C.B. Pp. xii+107. (London: J. Murray, 1910.) Price 2*s.* 6*d.* net.

THIS is an account of the history of weights and measures in England from the time of the Anglo-Saxons to the present day. It is meant to be of a popular character, and is written in an attractive manner, but as it includes the results of independent researches by the author, it may be of some interest to archæologists as well as to the general public. Sir Charles Watson appears to be an opponent of the introduction of the metric system in this country, and his book is in part intended to show that our present system rests on the experience gained by many centuries of legislation, and accordingly should not be abolished hastily in favour of a system of foreign origin and of comparatively recent date.

An interesting account is given of the various "pounds" which have been in use in England. The author is of opinion that the term "troy weight" is derived from an old English word "troi," signifying a balance, and that "avoirdupois" was a generic word used with respect to articles of considerable weight relatively to their value, which were sometimes weighed by a kind of Danish steelyard, or desemer, known as an "auncel." His identification of the gallon of Edward I. with the wine gallon of Queen Anne is not very convincing. He gives a good account of Gunter's chain, which he considers an excellent example of the kind of improvement that can be made with advantage in a system of weights and measures without introducing a new standard of measurement.

On the whole, the author is to be congratulated on having produced an eminently readable book on a subject which is often treated tediously. Some of his suggestions for the simplification of the British system given in the concluding chapter are deserving of consideration, but the proposal to abolish apothecaries' weight would be unlikely to meet with support in the professional circles mainly concerned.

On p. 24, line 8, "three-quarters of a yard" should apparently read "a yard and a half."

Newcomb-Engelmann's Populäre Astronomie. Vierte Auflage. In Gemeinschaft mit den Herren Prof. Eberhard, Prof. Ludendorff, Prof. Schwarzschild, herausgegeben von Prof. P. Kempf. Pp. xvi+772. (Leipzig: W. Engelmann, 1911.) Price 14 marks.

PRACTICALLY a generation has passed away since Newcomb's "Popular Astronomy" was first published. Many popular works have appeared since, but they have not supplanted the original work in its entirety, or provided a better model to which continual extensions could be added.

The main intention of the author has been kept in sight in the present edition. He did not cater for the professional investigator or the special student, but he aimed at placing before the general reading public a condensed view of the history, methods, and results of those portions of astronomical research that possessed a popular and philosophic interest. Like the last edition, the present has been entrusted to the staff of the Potsdam Observatory. This is fitting, since it is precisely in the department of astrophysics—the direction to which the energies of the Potsdam astronomers are more specially devoted—that the greatest progress has been made and the greatest need for revision exists. But other astronomers have ably cooperated. Prof. Schwarzschild has rewritten the section on the determination of orbits, and revised the chapter on cosmogony. Seeliger supplies the most recent details on the distribution of stars; Prof. Kobold revises the cometary statistics; Dr. Schweydar writes on the figure of the earth, and discusses recent hypotheses concerning its internal constitution. In this section we should have been glad to see more extended references to the work of Hecker.

Other sections which have been rewritten or extended are those on stellar parallax (Ludendorff), physical constitution of stars (Eberhard), motions of stars

(Ludendorff), variable stars (Kempf), new stars (Eberhard). On the general scaffolding that Newcomb contrived, later artists, it will be seen, have created a more complete and elaborate building.

Gehirn und Rückenmark. Leitfaden für das Studium der Morphologie und des Faserverlaufs. By Dr. Emil Villiger. Zweite auflage. Pp. vii+278. (Leipzig: W. Engelmann, 1910.) Price 12.80 marks.

WHEN the first edition of this book was reviewed in NATURE some four years ago, we then admired the lucidity of its style, and the excellent manner in which the author, Dr. Villiger, of Basle, arranged his description of the structure of the central nervous organ. The new edition is a considerable improvement upon the old. Beginning with a concise account of the embryology of the brain and spinal cord, the author proceeds to describe the gross anatomy of the brain, and illustrates his text by numerous excellent photographs and diagrams.

The second part of the work, dealing with the course of the various nerve-tracts and with the cranial nerves, is a model of luminous exposition. Many new diagrams have been substituted for those in the original edition.

The chief difference, however, is in the addition of an entirely new third part, consisting in a collection of more than fifty sections of the brain-stem. One set of these sections forms a series extending from the anterior end of the corpus callosum down to the corpora quadrigemina. The other series traces the structure of the various parts from the caudal end of the medulla oblongata upwards to the mid-brain. Each figure is accompanied by a full and descriptive text, so that the reader is provided with a fairly complete topographical atlas. Dr. Villiger's book bears the stamp of an expert teacher. It is difficult to give an adequate account of its many good points, and we trust that ere long it will become available to English readers in an authorised translation.

Thoughts on Ultimate Problems. Being a series of Short Studies on Theological and Metaphysical Subjects. By F. W. Frankland. Pp. xii+101. (London: David Nutt, 1911.) Price 1s. 6d. net.

THIS collection of studies on philosophical and religious subjects has now reached a fourth edition, which is sufficient proof that the author's treatment of profoundly important matters has appealed to a wide circle of readers.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Stinging Tree of Formosa.

THE stinging effect of the common nettle (*Urtica dioica*, L.) is so well known that even a cursory reference to it seems to be superfluous. This stinging power of Urticaceæ is found to culminate in the genus Laportea, which exhibits in certain species a most virulent effect enduring for some days, or even months, in response to a light touch on one of the leaves.

During my botanical tour in the southern part of Formosa in 1909 I observed, in the district of Kōshun, an endemic species of the stinging tree (*Laportea pterostigma*, Wedd.) growing not infrequently in the mountainous districts of that part of the island, where it is called by the natives "Chiao-jen-kou," meaning "Man-biting-dog." It is mentioned in the revised edition, completed in 1747, of a Chinese book, the *T'ai-wan-fu-chi*, or a "Topography of Tai-wan Prefecture [in the Island of Formosa]," vol. xviii., fol. 21,[1] where we observe the following statement:—

"'Chiao-jen-kou.' . . . This tree attains to a height of more than ten feet, with the leaves long and large, resembling those of the tobacco-plant, and furnished with stinging hairs, which, when they sting a man, enter the hair-follicles and become so irritating that if lightly rubbed the colour of the skin becomes red, and the pain continues for a day and a night, after which it ceases."

Dr. Augustine Henry, in his "List of the Plants of Formosa" (Trans. Asiat. Soc. Jap., vol. xxiv., Suppl., p. 88), has already made a reference to this tree, as well as to the *T'ai-wan-fu-chi*, by stating that it is "a small tree, the leaves of which sting violently, known colloquially and in the Gazetteer as 'Yao-jen-kou' [='Chiao-jen-kou']; " he refers to it again (*loc. cit.*, p. 12), saying that "the 'Stinging-Tree,' a species of Laportea, is very unexpected in its effects on anyone ignorant of its quality." Reference is also made to this tree in an article, by the same gentleman, on the "Botany of Formosa," published in the *Kew Bulletin*, 1896, p. 70.

My botanical friend who accompanied me during the greater part of my tour in Formosa, and has had considerable experience in connection with the flora of that island, told me the following anecdote when we both saw before us the stinging tree growing wild in the southern part of the island:—

"A Japanese traveller who happened to be alone in some mountainous district in Formosa, rubbed unconsciously a part of his body with a leaf of this tree, which stung him so violently that he ran in madness and cried in agony of pain, and it took a day or so before he recovered. In examining some leaves collected from the same tree, they were identified as belonging to those of 'Chiao-jen-kou.'"

After hearing the above anecdote, I suggested a Japanese name, "Mamushi-no-ki," or "Viper Tree," as a warning to all who hearing this name that they should not dare to touch the leaves in future. As I remember that I observed myself a small tree, partly cut down, close to a cottage situated near the coast in the small harbour of Tai-han-roku, it appears to me that this tree is not uncommon in the southern part of Formosa.

In Messrs. Forbes and Hemsley's "Index Floræ Sinensis," ii., p. 472, and in Drs. Matsumura and Hayata's "Enumeratio Plantarum Formosanarum" (Tokio, 1906), p. 382, this tree is enumerated, but no reference is made to its remarkable stinging effect. In Mr. Kawahami's useful "List of Formosan Plants," recently published by the Formosan Government, a Japanese name of "Irakusa-no-ki," or "Stinging-Nettle-Tree," has been newly coined. In consequence of its powerful effect of stinging, the Japanese name of "Irano-ki," or "Stinging Tree," might be more appropriate.

There are some other species of Laportea which exhibit, even when slightly touched, a remarkably poisonous effect. In Engler and Prantl's "Die natürlichen Pflanzenfamilien," iii., 1 Abteilung, p. 106, the following statement concerning *Laportea crenulata*, Gaud., of eastern India, is to be found:—"Bei leiser Berührung mehrere Tage dauernde Schmerzen hervorrufend." Weddell (in De Candolle's "Prodromus," xvi., par. 1, p. 85) made the following reference with regard to the stinging effect of the same species:—"Quod ad vires nocuas stimulorum attinet vid. monographiam meam [*i.e.* Weddell, 'Monographie de la famille des Urticacées,' in 'Archives du Muséum d'Histoire Naturelle,' ix., 1856]." In the *Gardeners' Chronicle*, 1882, vol. xviii., p. 465, we find the following extract from *Knowledge* concerning the stinging effect of this species:—"The Stinging Tree of Queensland, Australia, is a luxurious shrub, pleasing to the eye

[1] The revised edition, above referred to, of the *T'ai-wan-fu-chi*, has now become very rare in Japan. In 1895, when Formosa was ceded to Japan, some wood-blocks of the *T'ai-wan-fu-chi* were found to exist in Taihoku, and consequently a new impression was made by the order of the Formosan Government. But soon afterwards these wood-blocks were destroyed by a conflagration, with the exception of a few blocks, which are now preserved in the Government Museum at Taihoku. Even the new impression is now out of print, so that it is not too easy to obtain a copy in Formosa. I, however, lately secured a complete copy of an old (*i.e.* Chinese) impression in Tokio.

but dangerous to the touch. It grows from 2 or 3 inches to 10 or 15 feet in height, and emits a disagreeable odour. Says a traveller: 'Sometimes, while shooting turkeys in the scrub, I have entirely forgotten the stinging tree till I was warned of its close proximity by its smell, and have often found myself in a full forest of them. I was only once stung, and that very lightly. Its effects are curious. It leaves no mark, but the pain is maddening, and for months afterwards the part when touched is tender in rainy weather, or when it gets wet in washing, &c. I have seen a man who treats ordinary pain lightly rolling on the ground in agony after being stung, and I have known a horse so completely mad after getting into a grove of the trees that he rushed open-mouthed at everyone who approached him, and had to be shot. Dogs when stung will rush about whining piteously, biting pieces from the affected parts.'" Mr. N. E. Brown, of the Royal Gardens, Kew, made an interesting contribution (*Gard. Chron.*, *loc. cit.*, p. 567) of his personal experience concerning the virulent effect of the sting of this species in the palm-house at Kew. TOKUTARO ITO.

Tokio, January 25.

The Sailing-Flight of Birds.

SINCE Mr. F. W. Headley urges (February 16, p. 511) readers of NATURE to make observations on the flight of the albatross, possibly a few remarks may be of interest from one who, as a student of aërodynamical problems, has carefully watched such wonderful performances.

One point which has always struck me is that the albatross almost invariably flies in immense circles, ever varying in size and direction. Sometimes the bird will be high overhead, then, swooping down on a curve, will skim closely over the tops of the waves, then suddenly rising again will float away to perhaps half a mile off, gradually sweeping around, and perhaps again attaining a considerable elevation. It seems quite impossible to decide, from observation, whether the elevation is gained from uptending winds. Without doubt, the bird takes every advantage of each puff or eddy he can find, but he does *not* progress, as in Mr. Mallock's figure, steadily from wave to wave, rising and falling with the waves. Nor does he, so far as one can judge, invariably rise when facing the wind, and *vice versa*. That albatrosses, as well as other birds, seem always to soar in circles, may be due to the circumstances that, for instance, in following a ship, they have to circle round and round in order to keep near it, not being able to fly at such a slow speed as that of the ship (and therein is a hint to our cross-Channel aviators). So too vultures and eagles may soar around, not wishing to depart from the district which they are watching. But the question to which I have long wished for a reply is, "Can birds soar in a straight line?" I remember many years ago seeing, on the Nile, flocks of pelicans gliding along on outstretched wings. Now these birds were progressing up the river, performing actual journeys, but I cannot remember whether they were actually soaring in a straight line all the time.

I have frequently noted, what is patent to all, that in calms there is no true soaring; also I feel sure that there is no kind of motion of the wing such as Mr. Hearn suggests. One thing is certain, and that is that a soaring bird, especially the albatross, always progresses at great speed. Having once obtained the initial impulse, there is so very little head resistance offered to forward motion by the bird that the speed slackens but little. He progresses, as described by Langley, in the manner of a skater skimming over thin ice, travelling so fast that the ice has not time to break.

Much of interest on this matter is to be found in the old annual reports of the Aëronautical Society. In that for the year 1868 there is an interesting discussion in which Mr. Young is quoted as saying that he had noticed "the hollow form of birds' wings; these were not planes; indeed, a little consideration would show that the curved surface is better than a true plane. . . . He concluded that the best means of flight is by a curved wing." A great deal has been said on this subject during the last few years, but how many have read these old, and often instructive, discussions? B. BADEN-POWELL.

The Non-simultaneity and the generally Eastward Progression of Sudden Magnetic Storms.

Fact.

IT will be necessary, first, to my regret, to direct attention to some further errors in Dr. Krogness's communication in NATURE, December 8, 1910, p. 170, to which I made reply in the issue of January 5, p. 306. He questioned the correctness of our time of beginning of the disturbance, May 8, 1902, as recorded on the horizontal intensity curve at Potsdam, viz. 12h. 0m. Greenwich mean civil time, whereas his determination for the same station was 11h. 58m. In my reply, I stated (*idem*, p. 307) that Dr. Krogness must have made an error somewhere, for, upon repetition of our time scalings, based upon the data supplied us by the Potsdam Observatory, we got our identical result. I next wrote to the Potsdam Magnetic Observatory and requested that the time be scaled with all possible accuracy from the *original* magnetogram. Under date Potsdam, January 20, 1911, Dr. Venske gives the time in question as 11h. 59·7m., hence within 0·3m. of our time, but differing 1·7m. from that of Dr. Krogness.

Furthermore, in compliance with a circular request, I am receiving almost daily from observatories over the whole globe fresh data on the fifteen sudden disturbances, July 29, 1906, to September 25, 1909, first investigated by Mr. R. L. Faris for the five Coast and Geodetic Survey observatories. It will be recalled that Mr. Faris's data had furnished important testimony on the question as to the strict simultaneity of abruptly-beginning disturbances. Both Drs. Chree and Krogness have attempted to break down this testimony, but the data received thus far from other observatories are bearing out the conclusions previously drawn.

Table I. contains the time data for the very same disturbances chosen by Dr. Krogness. Confining our attention to the horizontal intensity disturbance curves, just as he does, we have first the mean time of beginning as derived from the five Coast and Geodetic Survey observatories (Faris's data, the means being formed by Dr. Krogness; for the last disturbance the record at Sitka was missing, so that in the mean only four observatories are embraced). Next is given the times of beginning for the Potsdam Observatory, first as derived by Dr. Krogness and employed in his communication (*idem*, p. 171), next as recently scaled by Dr. Venske at Potsdam, using the *original* magnetograms. Forming the differences P (Potsdam), U (United States), it is seen that for the Krogness scalings there are three plus differences, two minus ones, and one zero, resulting in an algebraic mean of but +0·03m. The case is, however, different for the next column, which depends upon the Venske, *i.e.* the *original* data of the Potsdam Observatory; there are now five plus differences and but one minus, the algebraic mean being +0·47m. or 0·44m. higher than that of Dr. Krogness. These differences (P-U) are small quantities, to be sure, but the interesting point is that, in every instance, for the Venske figures they are in the same direction as determined by me from the five Coast and Geodetic Survey observatories alone, and as published in *Terrestrial*

TABLE I.—*Greenwich Mean Civil Times of beginning of Disturbances in the United States and at Potsdam.*

Magnetism, vol. xv., p. 231, Table VIII., Nos. 20, 24, 25, 28, 30, 31. The letters E (motion of disturbance eastward or plus motion) and W (minus or westward motion) given in the last column are as taken from Table VIII. spoken of; note how the plus sign is linked each time with E and the minus with the W. Surely the most captious critic will hardly contend that this is mere chance.

As judged by the Venske data, Dr. Krogness's time scalings are in error from −0·5m. to +1·2m., and, on the average, +0·43m., his general tendency being to measure the Potsdam time *too low* by almost 0·5m. It must hence not be surprising that he failed to detect the generally eastward progression in the times between the United States and Potsdam, and was, instead, led to negative results; the difference of half a minute is precisely on the order of the required quantity.

Dr. Krogness, in his communication (*idem*, p. 171), unwittingly revealed also that the time scalings of his chief —Prof. Birkeland—were likewise untrustworthy. In order to get some definite information regarding the methods employed, Prof. Birkeland was next appealed to directly, but unfortunately in a reply received from him he failed to answer my question. It is recommended that all time data which appear in Prof. Birkeland's vol. i. (Norwegian Aurora Polaris Expedition, 1902–3) be used with extreme care by anyone who wishes to look into the matter of simultaneity of abruptly-beginning disturbances. I am not surprised now that Prof. Birkeland was unable to reach any definite conclusion himself on this interesting and important question, for his data lacked the necessary refinement.

Since I am on record as believing that no implicit reliance is to be placed upon simply one observatory, no matter how excellent its instrumental equipment and methods may be, Table II. is next given for the fifteen

disturbances spoken of above; in this all the observatories are embraced the data of which have been received to date, February 10, excepting one the time scalings of which differ occasionally 10m. or more from near-by institutions, and are doubtless subject to some error. The "North American group" embraces the six observatories Honolulu, Sitka, Baldwin, Agincourt (Canada), Cheltenham, and Porto Rico, the mean geographic position being 36·3° N., 101·7° W., of Greenwich; the "European group" gives the mean times for the seven observatories Stonyhurst, Greenwich, Uccle, Wilhelmshaven, Munich, Potsdam, and Katharinenburg, the mean geographic position being 52·4° N., 13·6° E., of Greenwich. It will be noticed that Kew is not included, for the simple reason that, although Dr. Chree scaled the required data some months ago, he has not yet published them nor forwarded them to me. The Greenwich data were received the earliest of all, viz. January 23, and those of the distant Observatory of Katharinenburg on February 9. The numbers attached to the various entries in Table II. correspond to those in my Table VIII. (*Terr. Mag.*, vol. xv., p. 231).

The last two columns ascribe the direction of progression of the disturbance according to the sign of the difference E–N, plus meaning east. First the direction is given as derived from the present investigation, which depends upon data over the region from Honolulu, 158° W., to Katharinenburg, 60·6° E., and next as obtained previously from the five Coast and Geodetic Survey observatories alone (Honolulu, 158° W., to Porto Rico, 65·4° W.). Comparing the two columns, it is seen that only in three cases out of fifteen, viz. Nos. 24, 26, and 29, do the letters clash; in other words, in 80 per cent. of the cases the directions, as determined from the limited portion covered by the United States observatories, agree with those now gotten for a considerably larger region. Moreover, Nos. 24 and 29 exhibit the interesting fact that while the disturbance each time progressed eastwardly in Europe just as it did in the United States, yet the mean time of occurrence for each is less in Europe than in North America. These are precisely similar cases to the disturbance of May 8, 1902, which seemingly began in the Atlantic and Europe, and then travelled eastward, being felt last in the United States. When the data for the observatories in Asia are available, the actual direction of progression of the two disturbances Nos. 24 and 29 will be known better. This shows, as I have already pointed out, how important it is to know approximately the region where the disturbance originated (cf. *Terr. Mag.*, vol. xv., p. 20). The result from No. 26 is more or less doubtful, evidently the point of beginning being not sufficiently sharp at all stations; three of the observatories mark their times doubtful, and two omit giving them.

Both columns unite in showing that the eastwardly progressing disturbances predominated over the westwardly ones in the ratio of about two to one. The average difference E–N, regardless of sign, is 0·68m., which was the average time required for a disturbance to pass from the mean position of the North American group to that of the European, or over a great circle distance of 75°. If the disturbance continued to progress at this rate, and were to make a complete circuit of the earth, it would take 3·3m., hence on the order of the quantities already announced. The linear velocity here concerned would be about 200 km. per second.

The available data on the non-simultaneity and progression of abruptly beginning disturbances have now been subjected to so many severe tests that it is difficult to see how anyone with an open mind can any longer doubt that some important discoveries concerning magnetic disturbances have been made. I should, indeed, be glad to be informed of any other facts in terrestrial magnetism which have stood as well the tests applied.

Dr. Chree, unfortunately, in his paper before the British Association last summer, and again before the Physical Society of London on November 11 last (Proceedings, vol. xxiii., part i., December 15, 1910 [49]), devotes chief attention to pointing out difficulties in explanation. He seems more concerned in determining why, according to his ideas, the phenomenon should not be rather in finding out whether it *is*. One of the chief purposes of my paper was to arouse further investigation on the part of others. Dr. Chree could not have done better than immediately to have published his own data in the same open manner that Mr. Faris had done. Instead, he labours to discredit the Coast and Geodetic Survey observations, and withholds his own from public scrutiny. In half the interval of time between the first and second presentation of his

paper, had Dr. Chree chosen, he could have had at his command data from Europe and Asia which, combined with his own, would have served admirably to have tested the main contentions. He might thus have been credited with a really helpful contribution to the subject; but no such attempt has been made.

In view of the discussions which have arisen with regard to time data from present magnetograms, I have made request of each observatory for a statement of the method employed. From the reports thus far received, it is found that no institution has made a more earnest attempt to allow for all sources of error than is the case at the Coast and Geodetic Survey observatories. It is evident that in several instances equal care, for one reason or another, is not given by others, but, judging from the fresh interest aroused by the present investigations, there is every reason to expect considerable improvement hereafter. This may be a sufficiently useful end to have achieved, even if nothing else had resulted from the researches.

Theory.

The hypothesis of ionic currents which I have employed in the study of magnetic disturbances thus far treated is based on the existence of a primary set of electric currents circulating around the earth overhead. Quoting from my paper No. 1 (*Terr. Mag.*, vol. xv., pp. 122–3):—

"Since magnetic observations made at various points on the Earth's surface have revealed the existence of a definite system of atmospheric electric currents, it follows at once that if the atmosphere is made more conducting at any point, an extra current will be started and set in motion by the pre-existent electromotive force or its equivalent. The direction followed by the new current depends upon its origin, upon the direction of the electromotive force at that point, and upon the deflecting effect of the Earth's magnetic field and of the Earth's rotation on the electric carriers. In other words, while we shall look chiefly to extra-terrestrial agencies for ionising the air and thus splitting it up into carriers of positive and of negative charges, we look to the atmospheric electric field and to the Earth's rotation for furnishing the energy necessary to drive the ions over the Earth and by their motion produce the effects observed during a magnetic storm."

In No. 3 (*idem*, vol. xvi., p. 34) I summarise the evidence available regarding the outside electric field as based upon the harmonic analyses of the earth's magnetic condition by Adams, Schmidt, and Fritsche. I show that its general characteristics are very similar to the supposedly internal magnetisation of the earth. The outside currents, if negative ones, would have to circulate around the earth from west to east, hence in the same direction as the rotation of the earth. Starting with these currents, I find it possible to account for the earth's own magnetisation if the earth's average magnetic permeability is on the order of 135 as referred to air and for a magnetising force of about 0·0024 C.G.S. This value, while seemingly large, is not impossible, judging from the experiments of Lord Rayleigh and of C. Baur on iron, using small magnetising forces. Furthermore, it must be borne in mind that we are absolutely ignorant as to what effect the great pressures existing at but a few kilometres below the surface may have on the permeability of magnetisable substances—possibly the effect of increased temperature with depth may be completely annulled by the comparatively more rapid increase in pressure.

In brief, I have set up the hypothesis that the earth is chiefly an electromagnet, the magnetising currents being outside, and consisting of negative electric currents circulating overhead in the same general direction as that of the earth's rotation. I follow out the consequences, and show that this hypothesis harmonises with the Gaussian analysis, from which it had been hitherto almost universally concluded that the magnetising causes must be contained chiefly *inside* the earth.

By thus putting the magnetic state of our planet primarily in the control of *outside* electric currents, many of the outstanding problems of terrestrial magnetism are greatly simplified. Any variation, periodic or spasmodic, in the intensity and direction of the magnetising currents must, of course, be followed almost immediately by corresponding changes in the earth's magnetisation. It thus becomes clearer now how, in the space of but a few minutes, such great changes can occur in the magnetic condition of our planet as are experienced during magnetic storms. Anything that will cause a change of conductivity in the strata containing the outside currents will evoke changes in the latter, which in turn are revealed in effects on our magnetic needles. There may be many such causes—the theory need not restrict itself to any one, as, for example, kathode rays.

Analysing the type of disturbance of which the one of May 8, 1902, may be taken as typical, it is seen that we have before us but a miniature reproduction of the earth's own magnetisation. In brief, a system has been found which will produce magnetic disturbance effects precisely similar to the permanent magnetic effects referred to the earth (*idem*, vol. xv., pp. 25–30, 117, and vol. xvi., pp. 33–48).

The type of disturbances which Prof. Birkeland refers to "equatorial" currents is thus found to be merely a general disturbance of the entire magnetic condition of the earth, of such a simple character that the first harmonic may give a sufficiently complete representation of the observed perturbations. The theory advanced in my papers is that the same electric-current system which may have to be held accountable for the production of the earth's magnetisation will also suffice for the production of the disturbances considered. I propose the name, therefore, of "simple magnetic perturbation," in place of Prof. Birkeland's "equatorial magnetic perturbation," adding the words "positive" or "negative," just as he does, according to whether the general effect is to increase momentarily the earth's magnetisation or to decrease it. Prof. Birkeland and I are not in agreement as to the direction in which the outside currents must go to produce the observed magnetic effects (*idem*, vol. xvi., pp. 33–48).

The careful reader will not fail to observe that the theory, as above briefly outlined, is considerably different from that which Dr. Chree imputed to me on p. 51 of his paper cited above. Furthermore, the calculation which he says he is unable to follow, although others have done so, was merely a preliminary attempt to account for the observed progression of sudden disturbances and to get some idea as to the order of the altitude at which the supposed currents would have to circulate. If Dr. Chree has something better to offer I shall be glad to know it. Such interest is being manifested now on all sides, that it will doubtless not be long before a fairly satisfactory theory will be forthcoming. Someone must make the attempt, however, to rear a structure; not all of us are willing to rest contented with merely pulling down. One correspondent has hit upon another promising clue, which is at present being tested. In the meanwhile, I believe our hypotheses have amply justified themselves by the many new questions raised and the fresh incentives given to investigation.

L. A. BAUER.

Washington, D.C., February 10.

Postscript.—From NATURE of February 2, just received, it is noticed on p. 461 that Prof. Schuster presented a paper before the Royal Society on January 26 entitled "The Origin of Magnetic Storms," in which a critical examination is made of the theory that magnetic storms are caused by streams of electrified corpuscles ejected from the sun. Prof. Schuster, after various calculations, reaches the following conclusions:—

"If magnetic disturbances are produced by rays emanating from the sun, it can therefore only be in an indirect manner. We may imagine that the injection of corpuscles ionises the upper portions of the earth's atmosphere, and consequently renders the already existing electromotive forces more effective, or we may imagine that the approach towards the earth's magnetic field of highly conducting material containing ions of both kinds acts by induction. The effect of such induction would primarily be an increase in the horizontal and a diminution of the vertical forces, while the currents induced in the earth, tending to diminish the horizontal forces, would, owing to the inertia, die out more slowly, so that a semi-permanent effect would be left after the storm."

It will be seen that the theory as set forth in my paper above is entirely in harmony with Prof. Schuster's conclusions; it is, in fact, largely based on his previous re-

searches. He and I are in agreement that the real origin of our magnetic disturbances is to be referred primarily to an outside electric system situated somewhere in our own atmospheric regions. I go one step further, and place in the same region the chief origin of the earth's own magnetisation.

In conclusion, it will be well to point out that the method used in my Table II. above to get the average rate of progression of sudden disturbances does not accentuate the actual time differences between distant stations, but tends rather to diminish them, as was the case with storms Nos. 24 and 29. In brief, as I have already hinted, the precise method of grouping of stations cannot be a fixed one, but must vary with the region in which the disturbance originated. When the data from the remaining parts of the globe have been received, this matter will become more evident. L. A. B.

Colliery Warnings.

MAY I say a word about colliery warnings to point out that it is not the high barometer that is of any importance, but the dryness of the air? It happens in our country that the high barometer and dry air generally come together.

Gas explosions in coal mines are trivial, and they occur on an average of more than one per day. It is when there is sufficient dust to make the explosion spread over a big area that an explosion is serious, almost without exception. Dry air is the danger, and should be the basis for "colliery warnings." JOHN HARGER.

University Club, Liverpool, February 21.

IN all collieries more than 600 or 700 feet in depth the air is always dry—somewhat drier in cold than in warm weather—and, consequently, coal-dust is always present in the workings provided there is no natural "seepage" of water into them. In these circumstances, the one essential element of a great explosion is always present.

Blasting shot, when fired under certain conditions, and comparatively small volumes of explosive gas when ignited, will always raise and ignite coal-dust the quality of which, as regards its contents in volatile matter and ash, lies between certain upper and lower limits. On the other hand, shots are always being fired, and larger or smaller accumulations of explosive gas are always being formed here and there in mines of this class, quite irrespective of weather conditions.

All that can be said as regards the influence of weather is that, other things being equal, a coal-dust explosion is more likely to occur in cold weather, when the mines are driest, than in warm weather, when they are not so dry, and with a falling rather than with a steady or rising barometer.

These subjects were fully discussed at the very inception of the coal-dust question, and Mr. Harger might do well to study what was then said about them.

As the issuer of "Colliery Warnings" so frequently advocates that special attention be paid to the condition of mines when the barometer is rising rather than when it is falling, I may perhaps be allowed, in this place, to correct a statement which lately appeared in a letter to NATURE, written by "The Author of the Warnings," to the effect that Mr. R. H. Scott and I were amazed (*sic*) to find that fire-damp was frequently reported to have been found in mines even when the barometer was steady and rising. We were not amazed, for we knew by the actual experience of one of us that, in consequence of falls of roof, damage to trap-doors, stoppings, brattices, and so on, which are amongst the commonest incidents in mining, the ventilation often becomes so stagnant at certain critical points that the air becomes explosive at or near these points before the defects can be rectified.

As a matter of fact, the principal province of the firemen is to guard against this very contingency. Consequently, when we saw appearances of fire-damp reported time after time with a steady or rising barometer, we experienced no surprise, but, perhaps rather unfortunately, considering the use the "Author of the Warnings" has made of the sentence in which we merely recorded a fact without further comment, we did not stop to explain what passed in our own minds at the time, but proceeded in the next following sentence to show that, when the records of a large number of mines were compared, the effect of these casual irregularities was practically eliminated altogether. It would have been fairer if the "Author of the Warnings" had quoted one more sentence (Quarterly Journal of the Meteorological Society, October, 1874).

W. GALLOWAY.

The Hydrogen Spectrum.

THE colour of the light which is emitted from the capillary of a vacuum tube containing pure hydrogen is the familiar vivid, deep pink, the prevailing tint being due to the predominating brilliance of the red line ($H\alpha$). When the same capillary is viewed from one end, however, the colour is a very pale pink, indeed, nearly white.

This interesting effect appears to be due to the different relative intensities of the lines $H\alpha$ and $H\beta$ in the two cases, for while $H\beta$ (and probably each of the other lines in the primary series) has an intensity appropriate to the length of the column of gas in the capillary, $H\alpha$ appears to suffer reduction.

In the course of some observations on the secondary spectrum of hydrogen, during which I had occasion to use the tube when placed against the slit of the spectroscope in the usual way, and also end on, I was greatly interested in this apparent variation in the intensities of the lines mentioned. The explanation which suggests itself is that $H\alpha$ is weakened by absorption in traversing the column of gas (although this distance is only about 5 or 6 cm. in my tube), but it is difficult to understand why this absorption should be specially selective for $H\alpha$ and not equally effective in the case of $H\beta$, which is also a very brilliant line, and to which one would imagine the same argument would apply. There appears to be no reason for attributing the effect to polarisation.

I have seen no notice of this effect, but I imagine it must be quite familiar to spectroscopists, and perhaps one of them who has devoted special attention to the hydrogen spectrum may be able to throw some light on the matter.

CHARLES W. RAFFETY.

Beechcroft, 2 Park Hill Road, East Croydon, Surrey, February 22.

Life and Habit.

ON p. 505 of NATURE for February 16, in a review of a new edition of one of Samuel Butler's books, these words appear:—"therefore the apparently unpractised but perfect pecking of a newly-hatched chick proves that the chick has done it before," &c.

Now, I have tried many experiments with chicks hatched out singly and away from a hen, but never has any chick attempted to peck until shown how to or made to walk over food which tickled its toes, and my opinion is that a chick might die of starvation while surrounded by food unless taught what to do. They are quick to take a hint, and will imitate the motion and action at once if a bent finger be worked up and down like the head of a bird when pecking; and, if once they feel a bit of food within their beaks, they know what to do with it as well as a new-born babe knows how to suck when anything is placed in its mouth, though they have never done it before. W. H. M.

February 20.

YOUR correspondent's remark is interesting, but, of course—as he himself indicates in connection with the babe—it does not invalidate Butler's argument. It can hardly be doubted that observation and imitation do not cover the ground, and that there is something calling for explanation in what is called "instinct"—a word which, it must be admitted, only disguises our ignorance of what it is. Butler's theory that "heredity is memory" is at least worth consideration. THE REVIEWER.

FOREST LIFE IN INDIA.[1]

IN these pleasant pages the author looks back cheerfully upon some of the events of thirty-five years in the Indian Forest Service, from the less responsible stage of assistant-conservator of forests, seeking the bubble reputation even in the tiger's mouth, to the more severe and formal stage of inspector-general, full of wise saws and modern instances. Of the gloom and monotony of existence far from the busy hum of men, and of the great and manifold dangers that surround life in a tropical jungle remote from all medical resources, he prefers, like a good Briton, to say nothing, though he must know all about them, and could no doubt make moan if he chose.

In the chapters covering the author's earlier terms of service as a junior executive officer in Oudh, and on the Nepal frontier, the moving incidents of sport predominate, and we are told much—though nothing, perhaps, very new—of the ways of the beasts that perish by the rifle. There are several accounts of the author's own experience of man-eating tigers; some, of course, tales of woe and death, but one—telling how an Indian peasant woman, with nothing but a sickle in her hand, attacked and beat off a man-eater that had seized her husband—might, if the heroine's name were known, be immortalised in the archives of the State.

FIG. 1.—The Baspa Valley. From "Forest Life and Sport in India."

With the advent of greater official responsibility the full tide of sport begins to ebb, and we are introduced to those questions of organisation and policy, which are the chief care of an administrative officer, and reveal the more serious purpose of the book. All these questions are treated with skill and tact. Among other things, we learn how far-reaching reforms of various kinds were effected, sometimes in the face of official indifference and misunderstanding; how native opposition to any interference with misconceived and misdirected "natural rights" was gradually overcome, so that suspicious villagers and destructive wild-men were at length converted into the ready tools of the forest conservator; and how institutions for the higher training of the forester are becoming engrafted on the educational system of the country. In short, we get from this excellent book not only a good idea of a forest officer's work in every grade, and of the main line of development of the Indian Forest Department, but also an insight into the many ways, direct and indirect, whereby well-managed forests contribute to a country's welfare.

This being one of the chief lessons of the book, we think that the author errs when, in discussing the relation of forest to ground-water, and so to agriculture, he speaks of forestry and agriculture as simple industries in comparison with the "*more important* manufactures that add to the national wealth." Surely at a time like the present, when England has grown all one-sided by neglect of agriculture, and whole masses of Englishmen deafened by machinery and blinded by smoke are in danger of losing their bearings, it were pity if a man who has lived half a lifetime in the precincts of Demeter did not boldly assert that as long as workmen require bread and butter and meat, so long must their most important accomplishments in the way of manufacture and all their additions to the national wealth wait upon the sturdy yeoman, who, like another Atlas, bears the civilised world upon his shoulders.

As a good Anglo-Indian of the olden style, the author thinks of his native subordinates and native servants as fellow-men, and always speaks kindly of them, and he regards red-tape with a noble aversion. On the other hand, he probably overrates the value of

[1] "Forest Life and Sport in India." By S. Eardley-Wilmot, C.I.E. Pp. xi+324. (London: Edward Arnold, 1910.) Price 12*s.* 6*d.*

the so-styled "expert specialist" of recent device; we have heard of this sort before, notably in connection with Indian agriculture, where he has been weighed and found—not altogether infallible. Life is compromise, and perhaps the best expert for India still is the service-man with a particular natural bent; the author almost admits this in his remarks upon the Forest School at Dehra Dun.

Much might be said of the illustrations, from photographs by the author's wife, that adorn the book. Some of them stir the heart "like the sweet sound that breathes upon a bank of violets."

FIG. 2.—A "Fire Line" in the Gonda Forests From "Forest Life and Sport in India."

DISTINGUISHED ANIMALS.[1]

IT may be said at once that any parent, guardian, uncle or aunt, who is on the look-out for a suitable gift-book to present to intelligent boys and girls, will find what he wants in Mr. Perry Robinson's "Of Distinguished Animals." A better school prize could not be given. But it is not quite the type of book suited for a review in NATURE, nor was its original prototype—a series of articles—quite up to what is expected now by the readers of *The Times*, which in the course of the year 1909 published a large proportion of this book under the title of "Studies in the Zoological Gardens."

This class of writing on natural history is somewhat out of date for grown-up readers, and, above all, subscribers to *The Times*. That *The Times* should deal with zoology or any other "ology" is what one would expect of it from time to time, but articles which it might publish on zoology, anthropology, botany, or horticulture, should invariably be written by specialists who can bring new facts to our notice and place before us convincing, perhaps startling, deductions. Otherwise, it may be said without peevishness that mature readers to-day are becoming a little tired of the "literary" treatment of such subjects, especially those connected with biology. The truth is of itself so marvellous, so spectacular, and interesting (if rightly put) that we do not wish for references to what imperfectly educated poets and prose writers thought of this or that beast or plant before the twentieth century, unless, of course, anything can be extracted from old writings throwing a fresh light on questions of geographical distribution, domestication, and the inter-relations between man and other forms of life.

The work under review is abundantly supplied with some of the best photographs that have ever been published of beasts, birds, and reptiles. But it does not contain much original matter in its letterpress, which is avowedly a long string of quotations intended to illustrate a number of remarkable types of beast, bird, and reptile, to be seen in the London Zoological Gardens. Not many of these quotations are new to the practised student of zoology, and a few of them are not quite true either in the facts they relate or in the deductions to be drawn from them. In the reference to the gorilla (p. 129), the assertion that the "gorillas" alleged to have been brought back by Hanno, the Carthaginian, from the west coast of Africa, "can hardly have been other than baboons," is not one which can be maintained, if the statements relating to Hanno's expedition are carefully considered in connection with the critical remarks thereon in Sir Thomas Bunbury's "History of Ancient

[1] "Of Distinguished Animals." By H. Perry Robinson. Pp. x+234. London: W. Heinemann, 1910.) Price 6s. net.

Geography." All that we know of this subject makes it nearly conclusive that Hanno's expedition reached as far as Sherbro Island, at the eastern limit of the Sierra Leone district, and that the wild, hairy men and women brought back by his people were the chimpanzees which still inhabit the forests of the Sherbro district. The Carthaginians were well enough acquainted with the baboon (which in those times was found not only in Egypt, but in the Tunisian Sahara), and would not have remarked on it with the same emphasis as they did, evidently, in connection with the chimpanzee skins.

FIG. 1.—Two Baby Anthropoid Apes." From "Of Distinguished Animals."

An allusion is twice made—not necessarily with credence—to Rudyard Kipling's story of "Bertran and Bimi." The theme of this was that a German residing in the Malay Archipelago possessed a huge orang which was so jealous of his newly-wedded wife, that upon the woman being left alone one day it tore away the thatch of her house, entered her bedroom, dragged her from the bed, and destroyed her. Here is an instance where "literature" steps in and tries to improve on fact, with disappointing results. Mr. Kipling's story was based on a real incident which occurred (to the knowledge of the present writer) in South Africa, where a huge Chakma baboon really did, in like circumstances, kill, or attempt to kill, the young wife of his master. Anyone who knows baboons and their extraordinary jealousy might well believe in the truth of such an incident, but as applied to the orang utan—to anyone who knows the

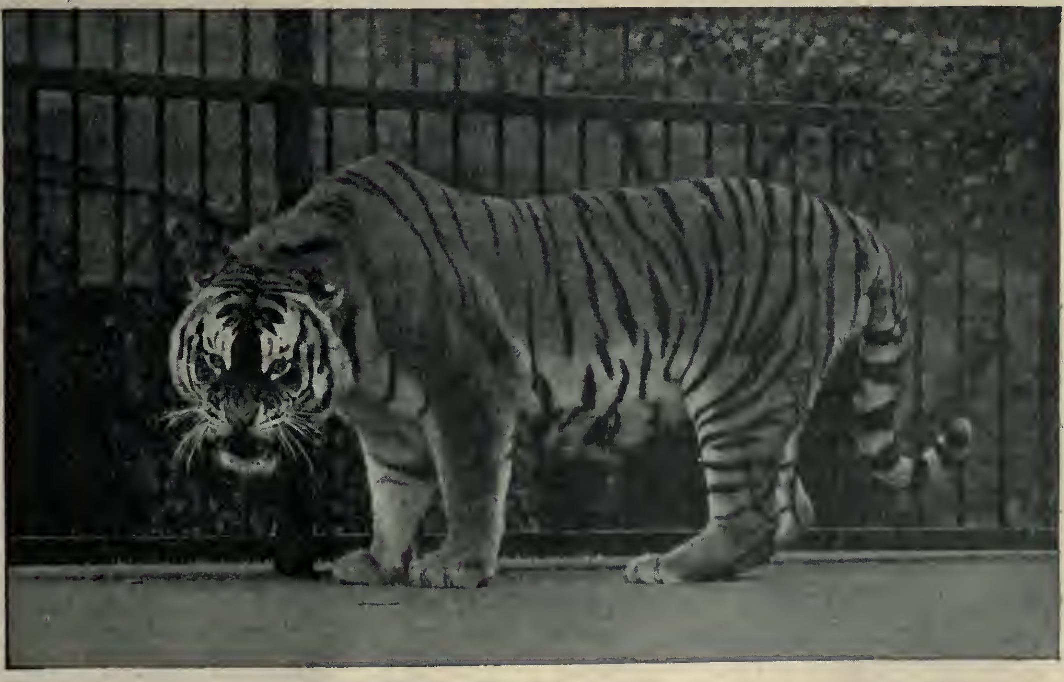

FIG. 2.—Siberian Tiger. From "Of Distinguished Animals."

orang—it is unbelievable and inapposite, and consequently is one of the few unconvincing stories in Kipling's otherwise admirable and truthful studies of the East.

But the author of "Distinguished Animals" cannot be held responsible for Mr. Kipling's rare slip in accuracy, and it is pleasanter to assert the general interest which the work under review possesses (apart from its remarkably good illustrations) for those who are not well acquainted with the history and habits of that marvellous collection of living creatures to be seen in Regent's Park. H. H. JOHNSTON.

THE KANGRA EARTHQUAKE OF APRIL 4, 1905.[1]

DESTRUCTIVE earthquakes are, fortunately, rare events, and when a civilised country is visited by one, the talk of investigating and of writing the report, which is now considered obligatory, falls necessarily on someone who has often more regular occupation. Hence it comes that we have to wait years for a connected account of a great earthquake, and that which visited the Punjab on April 4, 1905, is no exception; after the lapse of more than five years, with all the dignified delay, and, it must in fairness be added, all the thoroughness worthy of a great Government, the report on this earthquake, by Mr. C. S. Middlemiss, has appeared.

Nor could the memoirs have appeared more opportunely. The glamour of the great disaster which followed on the Californian earthquake, the remarkable character of the earth-movements which took place along the length of the San Andreas fault, and especially the fact that a very large part of the peculiarities of distribution of the shock seemed explicable on the hypothesis that fault and earthquake were related as cause and effect, have all given impetus to the popular notion that earthquakes are always a necessarily due to fracture. Yet even where faulting is observable there are generally indications that the fault is certainly not the sole cause, if it may be properly regarded as a cause of the earthquake; and now we have an account of a shock comparable in extent and violence with the Californian earthquake examined with great care and thoroughness of which the reporter writes that:—

> it may come as a surprise to many to be assured that the Kangra earthquake presents no evidence at all in support of this view: not a single railway has recorded any damage to the track, not a single road or path has been deflected, raised or lowered, no rivers or streams have changed their courses or been temporarily dammed up—except as due directly to landslips from slopes of such steepness that they might as easily have occurred after a heavy torrential rainstorm.

The greater part of the report is taken up with details of damage done to buildings, the sensations of observers and other stock subjects, in all of which little or nothing of novelty can be found; but when we come to the discussion of the cause of the earthquake there is much that is interesting and suggestive. The author, after discussing the nature of the origin, finally adopts the conclusion that there were two centres of origin, one in the Kangra valley and the other in the Dehra Dun. He points out that these two regions lie in imbayments of the great faulted boundary between the rocks of the Himalayas proper and the Tertiary beds originally formed as fringing deposits of Himalayan débris.[1] Moreover, it is just in these imbayments that an exceptional development of coarse boulder deposits indicates the position where great rivers issued from the mountains, where sedimentation was in excess, and where, in the subsequent compression and folding of strata, irregularities of packing might be expected to occur. So the conclusion is reached that the earthquake was a tectonic one, due to a sudden rupture or release of

FIG. 1.—Fallen Rock near Manoli. From "The Kangra Earthquake of April 4, 1905."

[1] Memoirs of the Geological Survey of India, vol. xxxviii. "The Kangra Earthquake of April 4, 1905." By C. S. Middlemiss. Pp. x+409+xxi+30 plates. (Calcutta: Geological Survey; London: Kegan Paul and Co., Ltd.; Berlin: Friedländer and Sohn, 1910.) Price Rs. 5.

[1] NATURE, March 1, 1906 (vol. lxxiii., p. 418).

strain at two places where the strain was specially great owing to resistances to the well-established forward march of the overthrusting foot of the Himalayan range.

All this is perfectly clearly put, the argument is logically arranged, and the conclusion is perfectly orthodox; but yet we must confess that in reading Mr. Middlemiss's description we were struck by many indications of the absence of direct connection between earthquake and geological structure. The principal focus of maximum intensity extends from the sub-Himalayan area across the great boundary fault, which is by far the grandest structural feature of the region; and the subsidiary focus in the Dehra Dun shows no tendency to a concentration of violence along any particular line or connection with any known structural feature, and from this area some observations are recorded which seem to be of importance so far as the origin of earthquakes is concerned. An old line of levelling from Saharanpur to Mussooree was gone over again after the earthquake with the result that although the relative levels of the extremities of the line were unchanged, it was found that the intervening bench marks in the Dehra Dun and the Siwaliks showed an elevation of from 4 to 5 inches. As no alteration in the relative level of Dehra Dun and Mussooree had been noticed when this section was re-levelled in May, 1904, it is practically certain that the change took place at the time of the earthquake. Now if the results are examined it may be noticed that elevation was not confined to one station, as might be expected had it been due to shifting of the opposite sides of a fault, but is rather a general bulging upwards, such as might be produced by a sudden increase in volume of the material underlying the region of greater violence of shock.

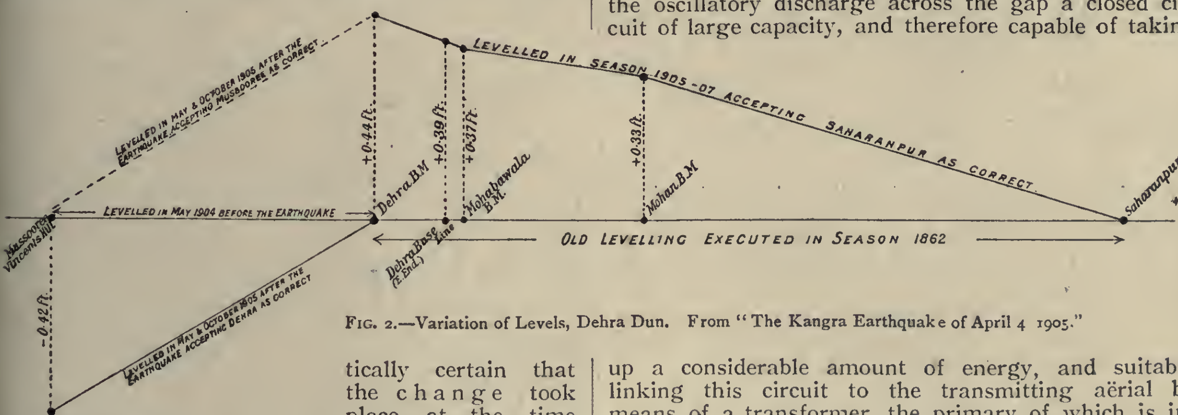

Fig. 2.—Variation of Levels, Dehra Dun. From "The Kangra Earthquake of April 4 1905."

These, however, are matters of inference and interpretation, and whatever may be the ultimate trend of thought as concerns them, the memoir under review will stand as an important contribution to knowledge which will have to be studied and reckoned with by all who attempt to deal with the vexed question of the nature and origin of earthquakes.

WIRELESS TELEGRAPHY SYSTEMS.

The action brought by Mr. Marconi and Marconi's Wireless Telegraph Co., Ltd., against the British Radio-Telegraph and Telephone Co., Ltd., for infringement of patent No. 7777 of 1900, concerning improvements in apparatus for wireless telegraphy, has been concluded, and Mr. Justice Parker delivered judgment on February 21 in favour of the plaintiffs.

The patent in question refers to an arrangement of the sending and receiving circuits in such a manner as to make telegraphy possible over increased distances by means of spark methods. In the methods in which spark-dischargers are used, a spark is caused to bridge the gap by the application of a direct-current or alternating-current supply, and it is arranged that the discharge thus produced should form part of a circuit in which high-frequency oscillations may be set up. This circuit must contain a capacity and inductance, and the charge and discharge of the capacity taking place through it will be of an oscillatory nature if the resistance of the cricuit be not greater than $\sqrt{\frac{4L}{K}}$, where L and K represent the inductance and capacity of the circuit. When the resistance is greater than this value, the discharge is not of an oscillatory nature, and is therefore unsuitable for the production of waves for wireless telegraphy.

In early methods of working the gap was placed directly between the aërial and an earth-plate, and the discharge produced by connecting an induction coil across the gap. The oscillating circuit consisted of the spark-gap and the capacity and inductance of the aërial, and the energy that could be radiated was small owing to the very small capacity of the aërial. The receiving circuit consisted of an aërial connected to earth through a coherer, which formed part of a relay circuit actuating a Morse printing instrument.

The improvement constituting the subject-matter of the patent under discussion consists in providing for the oscillatory discharge across the gap a closed circuit of large capacity, and therefore capable of taking up a considerable amount of energy, and suitably linking this circuit to the transmitting aërial by means of a transformer, the primary of which is inserted in the closed circuit, and the secondary of which is connected in the aërial. By this means oscillations of great energy are able to be set up in the closed circuit, and if the aërial circuit be tuned to have the same frequency of oscillation as this circuit, and be loosely coupled to it by the transformer, long trains of waves of a single frequency will be radiated by the aërial, which is, in virtue of its open circuit, a good radiator of the energy gradually supplied to it by the good oscillator formed by the closed circuit.

A similar idea underlies the arrangement adopted for the receiving circuit, in which a good absorber consisting of an open circuit containing the aërial is linked by a transformer to a poor radiator, and consequently a good accumulator of energy consisting of a closed circuit.

The apparatus of the British Radio-Telegraph Co. is substantially similar to that described above, with the exception that the oscillating and radiating circuits at the transmitting end, and the receiving and storing circuits at the receiving end, are connected by means of a single-coil transformer or auto-transformer instead of a two-coil transformer, as is used in the Marconi arrangement.

A considerable portion of the proceedings was occupied in the discussion whether the use of a single-coil transformer in the place of a two-coil transformer constituted an infringement or not, and the judgment

upheld the contention of the Marconi Co. that the two kinds of transformers are electrically equivalent, and that the apparatus of the defendants was an infringement of their patent.

The defence disputed the validify of the contested patent, and attempted to prove anticipation, basing the contentions principally on the patents granted to Sir Oliver Lodge and Prof. Braun. It is indeed a fact that the apparatus described by both these inventors contain examples of inductive couplings between the aërial and the oscillation-generating circuits, but it was successfully argued that neither of them had claimed the special kind of loose coupling or the tuning of the circuits that are essential to the satisfactory working of the Marconi system, and are fully set out in the Marconi patent specification. Other scientific investigators were mentioned, such as Henry, Tesla, and Elihu Thomson, who have employed coupled circuits, but their use of a transformer merely to raise the potential of the electrical oscillations produced by the discharge of Leyden jars was not able to be proved to constitute an anticipation or prior user of the essential features of the patent that has now been upheld.

The decision in this case has created a situation the outcome of which it is difficult to foresee, but there is no doubt that a number of companies now working systems similar to that of the Marconi Company will need to close their operations or to change their systems. This will have a marked effect on the grouping of wireless telegraph companies that is being carried out in England and on the Continent at the present time.

A. J. MAKOWER.

NOTES.

THE following fifteen candidates have been selected by the council of the Royal Society to be recommended for election into the society:—Prof. H. T. Barnes, Prof. A. J. Brown, Prof. J. B. Cohen, Prof. W. E. Dixon, Prof. F. G. Donnan, Major E. H. Hills, Dr. W. H. Lang, Prof. J. B. Leathes, Prof. E. A. Minchin, Prof. R. Muir, Mr. R. D. Oldham, Mr. R. I. Pocock, Prof. A. W. Porter, Mr. H. W. Richmond, and Mr. G. G. Stoney.

UNDER the auspices of the Advisory Committee for the Investigation of Plague in India, Dr. G. F. Petrie, of the Lister Institute, left London on February 20 *en route* for Harbin, where he intends to prosecute investigations into the spread of pneumonic plague in Manchuria. Opportunities for extended research into this highly contagious and extremely fatal form of plague infection have only rarely presented themselves, and as all available information points to the fact that the disease in Manchuria is almost exclusively of the pneumonic type, it is hoped that Dr. Petrie's investigations may shed some light on the factors which determine the incidence and spread of this particular variety. With matters of administration and sanitary measures Dr. Petrie will not be concerned. As one of the bacteriological experts whose work in Bombay (1905–7) proved conclusively the *rôle* played by the rat flea in transmitting bubonic plague from rat to man, Dr. Petrie obtained an intimate acquaintance with the disease in its epidemiological and bacteriological aspects, and recently he has been engaged, at the request of the Local Government Board, in determining the extent of the rat infection in Suffolk. The precise form which Dr. Petrie's investigations will assume in Manchuria cannot be determined until the local conditions prevailing in the plague-stricken area and the facilities available for scientific inquiry are known. Dr. Reginald Farrar, one of the medical inspectors of the Local Government Board, is also on his way to Harbin as the British representative on the International Plague Commission convened at the request of the Chinese Government.

IN the Prussian Diet of February 18, Prof. Kirchner, a well-known epidemiologist and administrator in the service of the Ministry of the Interior, is reported to have said that, during the last few weeks, three cases of plague had occurred in London, the infection being conveyed by ship-rats. This statement has been officially denied, and it is probable that Prof. Kirchner had in mind the two isolated cases of plague which occurred in ships on the Thames four months ago (see *The Times*, October 14 and 15, 1910). With the exception of a few imported cases on ships arriving at the docks, no cases of plague have been reported in London since the year 1679. An interesting account of such imported cases in recent years is to be found in *The Times* of February 20. With regard to rat infection, three rats which had probably escaped from a ship were examined at the London Docks in November last, and two of them were found to be suffering from plague, but at present there is no evidence of the existence of a plague epizootic among rats in the London Docks area. The destruction of rats, which was instituted in 1908 owing to the existence among them of a disease declared to be a mild form of plague, is still carried out at the London Docks, and careful precautions are being taken to prevent rats in ships from infected ports from escaping ashore, and possibly initiating an epizootic among the shore rats. Large numbers of cats are also maintained in the various warehouses and sheds.

THE death of the well-known Indian pteridologist, Col. R. H. Beddome, in his eighty-first year, took place on February 23 at his residence, "Sispara," West Hill, Putney. Educated at Charterhouse, Col. Beddome entered the Indian Army in 1848, and became quartermaster and interpreter of the 42nd Madras Infantry in 1856. A keen student of natural history, whose scientific tastes were well known, he was selected to act as principal assistant to the conservator in the newly organised Madras forest department in 1857; three years later he became conservator himself, and held this position until his retirement in 1882. His transfer to the Forest Department led him to give especial attention to botany, more particularly with regard to forest needs, and led to the preparation of a work on "The Trees of the Madras Presidency," published in 1863, followed by an excellent "Flora Sylvatica" of southern India, two quarto volumes, with plates and descriptions of 400 species, published between 1869 and 1874. A professional "Report upon the Nelambur Teak Plantations" was published by Government in 1878. His leisure, however, was given to the systematic study of other groups of plants, one of his earliest papers, published in 1859, being an interesting attempt to reduce to order the south Indian species of the difficult genus Impatiens. In 1863 appeared Beddome's important work "The Ferns of the Madras Presidency," a quarto volume of descriptions and plates which at once stamped him as an authority of this family. The issue between 1865 and 1870 of a similar work on "The Ferns of British India," with descriptions and figures of species not dealt with in the earlier work and the Supplement to that work issued in 1876, only served to confirm the position of authority he had been by common consent accorded. But ferns did not entirely absorb his attention, for between 1869 and 1874 Col. Beddome issued a volume of "Icones Plantarum," with descriptions and figures of 300 interesting species from southern India and Ceylon. Before he left India, he placed students of ferns under a further obliga-

tion by the preparation of "Handbook of the Ferns of British India," embodying his rich store of information regarding the family, illustrated by reduced copies of the illustrations to his own earlier and more costly works. This handbook appeared in 1883, immediately after his retirement.

THE King of the Belgians has made a donation of 500*l.* to the funds of the Liverpool School of Tropical Medicine.

M. EUGÈNE TISSERAND has been elected a member of the Paris Academy of Sciences in succession to the late Prof. Tannery.

BY his will, M. Auguste Loutreuil, the son of a small French farmer, who later became a wealthy contractor in Russia, has left 284,000*l.* towards the promotion of science in France. The University of Paris will receive 100,000*l.*, the Academy of Sciences 140,000*l.*, the Pasteur Institute 4000*l.*, and a sum of 40,000*l.* is to provide a fund for scientific research.

DR. BASHFORD DEAN, professor of vertebrate zoology at Columbia University, who was curator of the department of ichthyology and herpetology of the American Museum of Natural History from 1903 until last year, when he resigned, has accepted an invitation to resume that post.

PROF. F. B. LOOMIS, of Amherst College, Mass., will start early in July, accompanied by three of his students, on an expedition to Patagonia. Their principal purpose will be to collect fossils and study the geological problems of the country between the Santa Cruz and Deseado rivers. The expenses of the expedition will be met by the "class" of 1896.

AMERICA has lost one of her pioneers in physical training by the death of Dr. Edward Hitchcock, in his eighty-third year. Since 1861 he had been professor of hygiene and physical education at Amherst College, which gave him at the same time a general oversight of the health and exercise of its students. His work in that capacity had a wide influence, and within twenty years after his appointment fifty American colleges had organised departments of hygiene on similar lines. Dr. Hitchcock was the author of text-books on physiology and anatomy.

A BILL to prohibit the sale, hire, or exchange of the plumage and skins of certain wild birds was read a first time in the House of Commons on February 22. In introducing the measure, Mr. Alden said the Bill had been before a Select Committee of the House of Lords and had been approved unanimously, while in the last Parliament there were only two members who were against it. Twenty-one of our colonies are in favour of the Bill, and possess powers to prevent the export of the plumage of rare birds.

WE learn from *The British Medical Journal* that a lectureship has been established by the National Health Society as a memorial to the late Lady Priestley, who was one of the original members of the committee when the society was started some thirty years ago, and attended all the meetings until within a few months of her death. Three lectures have been arranged for March, the first by Sir E. Ray Lankester on living microbes, the second by Sir Almroth Wright on bacteriology and hygiene, and the third by Mr. Stephen Paget on Pasteur and his work.

A NEW biology and botany section has been added to the Bristol Museum. The new room has been provided by Lady Smyth, and is to be known as the "Dame Emily Smyth Room." The room has been made especially strong in its exposition of the kitchen-garden, fruit-tree, and agricultural pests of the west of England. At the opening ceremony on February 21, the curator, Mr. H. Bolton, said the authorities look forward to the economic biology department becoming practically useful to the farmer, to those who possess orchards, to the small growers, and to every man who loves plants and flowers and cultivates them for his pleasure or profit.

THE summary of the weather for the first eight weeks of the present year, issued by the Meteorological Office, shows that the rainfall for the period was deficient over the entire kingdom except in the north and west of Scotland. The greatest deficiency in any district is 2·83 inches in the south of Ireland, and this is closely followed by 2·74 inches in the south-west of England and 2·53 inches in the Channel Islands. In the Midland counties the deficiency for the two months amounts to 1·81 inches, and in the south-east of England to 1·56 inches. The largest aggregate rainfall for the period in any district is 10·80 inches in the north of Scotland, and the least 1·95 inches in the Midland counties. The rainy days range from 39 in the north of Scotland to 22 in the Midland counties. The mean temperature and the duration of bright sunshine are both in fair agreement with the average. At Greenwich the mean temperature for January was slightly below the normal, and in February it was above the normal to about the same extent, so that the mean of the two months is in absolute agreement with average conditions. Frost occurred in the shade at Greenwich on eight nights, both in January and February. Gales and strong winds were experienced frequently during February over the entire country, and there was a marked preponderance of westerly winds.

BEFORE the Royal Geographical Society on February 27 Dr. W. T. Grenfell, C.M.G., described the most important features of Labrador, a land still hardly known beyond its borders. The Vinland of the Norse sagas, its resources are great, but the polar current dominates its climate, and its southern latitude provides it with a short summer, which has not the continuous sunshine of Alaska and other places farther north. Cold soil and the dryness of the winds cause the stunted nature of many plants, a larch at the south end of Labrador being but 9 inches high and three-eighths of an inch in diameter, though it showed thirty-two years' growth. Except by Prof. R. A. Daly and Mr. A. P. Low, no serious geological investigation has been undertaken; mineral deposits seem to be abundant, but such prospectors and others as have visited the region have worked but for short periods. On the evidence of beaches and glacial deposits, Labrador was said to be rising, possibly as much as 15 or 20 inches per century according to some estimates. The coasts are still but imperfectly charted, and parts are dangerous, but harbourage is plentiful, and the numerous islands and the narrow waterways furnish many facilities for coastal navigation.

IN a former issue of NATURE it was announced that, in connection with the Royal International Horticultural Exhibition to be held in the grounds of Chelsea Hospital in May, 1912, there is to be a scientific section, and a congress will be arranged for the discussion of horticultural education and matters of scientific interest. A special committee has been appointed to look after these subjects, and the first meeting has been held. The chairman of this committee is the Rt. Hon. A. H. Dyke Acland, P.C., and Mr. F. J. Chittenden will act as honorary secretary. The members include Mr. E. A.

Bowles, chairman of the Royal Horticultural Society's scientific committee, Prof. W. Bateson, F.R.S., Prof. Bayley Balfour, F.R.S., Sir Thomas Elliott, K.C.B., Mr. Anderson Graham, Prof. Bretland Farmer, F.R.S., Mr. George Gordon, Mr. H. Rider Haggard, Sir Everard im Thurn, K.C.M.G., Dr. D. Jackson, Dr. F. Keeble, Mr. Donald MacDonald, Mr. W. Marshall, Mr. F. W. Moore, Mr. Spencer Pickering, F.R.S., Lieut.-Colonel D. Prain, C.I.E., F.R.S., Dr. A. B. Rendle, Mr. T. A. H. Rivers, Mr. A. G. L. Rogers, Prof. E. S. Salmon, Mr. A. W. Sutton, Prof. Somerville, Mr. H. J. Veitch, Prof. S. H. Vines, F.R.S., and the Rev. W. Wilks. Whilst the exhibition will be one of the chief spectacular attractions of the London season of 1912, the unique opportunities afforded by the presence of experts from every country will be utilised to the fullest extent for the advancement of horticultural science.

The Colonial Office announces that, to further the work of the African Entomological Research Committee, Mr. Andrew Carnegie has placed at the disposal of the committee a sum of 1000*l.* a year for three years to defray the cost of sending a few suitably qualified young men to the United States to study the practical applications of entomology. Three of these Carnegie scholars have been selected, and two are now at work in the States. The fact that Dr. L. O. Howard, chief of the Bureau of Entomology at Washington, is interesting himself, is a guarantee that all facilities will be given to the scholars, and the scheme will be of great value to British administration by providing well-trained entomologists for employment by the different Colonial Governments. The research committee was appointed in June, 1909, to promote the study of the insects which spread disease in Africa. Lord Cromer is its president, and it includes eminent authorities on entomology and tropical medicine. The scheme has been taken up by the African colonies and protectorates, and the material already received at the committee's office in the Natural History Museum at South Kensington has increased our knowledge of the insect pests of Africa. The collections of insects, after being identified and recorded, are being distributed to the schools of tropical medicine, universities, museums, or other institutions where they are likely to be of value. Further particulars may be obtained from the secretary of the committee, Mr. Guy Marshall, British Museum (Natural History), South Kensington, London.

A Bill to promote the earlier use of daylight in certain months yearly, and for other purposes relating thereto, has been introduced into the House of Commons by Mr. Robert Pearce. The chief clauses of the measure are as follows:—(1) From 2 o'clock in the morning Greenwich mean time in the case of Great Britain, and Dublin mean time in the case of Ireland, of the third Sunday in April in each year, until 2 o'clock in the morning Greenwich mean time in the case of Great Britain, and Dublin mean time in the case of Ireland, of the third Sunday in September in each year, the local time shall be in the case of Great Britain one hour in advance of Greenwich mean time, and in the case of Ireland one hour in advance of Dublin mean time, and from 2 o'clock in the morning Greenwich mean time in the case of Great Britain, and Dublin mean time in the case of Ireland, of the third Sunday in September in each year until 2 o'clock in the morning Greenwich mean time in the case of Great Britain, and Dublin mean time in the case of Ireland, of the third Sunday in April in each year, the local time shall be in the case of Great Britain the same as Greenwich mean time and in the case of Ireland the same as Dublin mean time. (3) Greenwich mean time as used for the purposes of astronomy and navigation shall not be affected by this Act. (4) This Act shall apply to the United Kingdom of Great Britain and Ireland, and may be cited as the Summer Season Time (Great Britain and Ireland) Act, 1911. We have on several occasions expressed the opinion that the changes contemplated by the Bill are unnecessary and undesirable, and we trust that the measure will meet the same fate as that of previous attempts at so-called "daylight saving."

The London County Council is doing good service to anthropology by developing the Horniman Museum at Forest Hill. It has now published, at a nominal price, under the title of "A Handbook to the Stages in the Evolution of the Domestic Arts," a useful introduction to the science of technology, prepared by the curator, Dr. H. S. Harrison, under the advice of Dr. A. C. Haddon. Curators of provincial museums might well consider the advisability of adapting this to the collections under their charge.

In the tenth number, vol. ii., of the Memoirs of the Asiatic Society of Bengal, recently issued, Mr. H. H. Hayden, of the Geological Survey of India, under the title of "Notes on some Monuments of Afghanistan," describes, first, some of the Buddhist Topes near Kábul, and has been able to correct a mistake of James Fergusson in his "History of Indian Architecture," who confuses the Munár-i-Surkh with the Munár-i-Chakri. It is regrettable to learn that the platform of the latter is in so ruinous a condition that, if immediate action be not taken, this interesting monument will inevitably fall. It may be hoped that the Viceroy may be able to put some pressure upon the Afghan authorities in order to avert this catastrophe. He also gives an interesting series of photographs of the celebrated Buddhist carvings at Bámián, and is able to give some new information about them. Occasion was also taken to photograph the tomb of the Emperor Bábar, who died at Agra in A.D. 1530 and was buried at Kábul. It is now possible, for the first time, to give in Persian and English the inscription on his tomb.

In a sixth report on research work, Dr. A. C. Houston, director of water examination, Metropolitan Water Board, gives details of an investigation on the comparative vitality of "uncultivated" and "cultivated" typhoid bacilli in artificially infected samples of raw river water, with special reference to the question of storage. In a previous investigation on the same subject (see Nature, vol. lxxviii., 1908, p. 377) it was found that in raw river water inoculated with ordinary laboratory cultures of the typhoid bacillus, in one week there was a percentage reduction in the number of bacilli of 99·9, but that a resistant minority of bacilli persisted up to nine weeks in the inoculated water. In the present work the raw river water (5 litres, kept in a partially stoppered bottle in a cellar) was inoculated with typhoid bacilli obtained by centrifugalising the infected urine of a carrier case which had come under the observation of Prof. McWeeney, of Dublin. In this way typhoid bacilli derived directly from the patient, without artificial culture, were added to the water, as would be the case in the natural infection of a water supply. At the end of one week after inoculation, examination showed that the initial number of 770,000 typhoid bacilli per c.c. of water was reduced to 4 per c.c.—a reduction of more than 99·99 per cent. Five subsequent examinations made from the fourteenth to the thirty-fourth day after the commencement of the experiment failed to isolate the typhoid bacillus from 100 c.c. of

the water. A second similar experiment gave corroborative results. In addition, Dr. Houston on several occasions drank half a pint of the water after the twenty-third day without ill effect! In another experiment water was inoculated with the typhoid bacillus derived from the same source, but cultivated for several generations on artificial media. The organism in this case was isolated up to the sixth week after inoculation into the water. The conclusion, therefore, is that "uncultivated" typhoid bacilli rapidly perish in raw river water, and that even a week's storage of raw river water is an enormous protection against typhoid infection from such a source.

IN the *Museums Journal* for January Dr. R. F. Scharff, of the National Museum of Ireland, Dublin, describes a dry system of macerating bones for use as exhibits. Formerly this was effected in water tanks, which proved so offensive on sanitary grounds that it was necessary to discontinue their use. Dr. Scharff has now discovered that the object can be satisfactorily attained by covering the bones with dry sea-sand, the bacteria almost wholly performing the work of maceration. Small skeletons are enclosed in boxes filled with sand, and the task of rearranging the bones when they are clean is thus greatly facilitated.

IN *Novitates Zoologicae* for December, 1910, vol. xvii., p. 445, pls. viii., ix., the Hon. Walter Rothschild gives coloured plates of the sea-elephants of Guadaloupe Island and the Falklands. The former is identified with the typical Juan Fernandez sea-elephant described by Linnæus as *Phoca leonina*, which appears to make periodical migrations from that island to Guadaloupe and back. Despite the much greater length of the proboscis in the males of the Juan Fernandez as compared with the Falkland animal, the author points out that other forms indicate a transition in this respect between the extremes, and he therefore proposes to regard all the local forms as races of a single species. This is, perhaps, the most satisfactory conclusion of a problem which has given rise to a considerable amount of discussion and confusion.

THE former existence of one imported giant land tortoise in Ceylon has long been known to naturalists, but it is remarkable that it should have been left to a casual correspondent of an English journal to supply evidence of the occurrence of a second. The first specimen, according to a letter from Mr. Pearson, director of the Colombo Museum, in *Spolia Zeylanica* for December, 1910, was found in Colombo when Ceylon was first occupied by the British in 1796. It was then living in the grounds of a villa called Uplands, in Mutwall, near Colombo; in 1894 it was removed to the Victoria Park, where it survived only a week. It is now preserved in the Colombo Museum, and is identified by Mr. Pearson with *Testudo gigantea* of Aldabra. The length of the shell is 40 inches. In *Country Life* of July 9, 1910, appeared a photograph of a giant tortoise living at Matara, near Galle, taken by Mr. Stanley Mylius, which is reproduced by Mr. Lydekker in an article on giant tortoises in *Science Progress* for October, 1910. That specimen, which is referred to *T. gigantea*, the author thought might be distinct from the Colombo tortoise, and that it is so is indicated at the close of Mr. Pearson's letter. In Mr. Lydekker's article the length of the shell is given as 53½ inches, and it may be that this refers to the Matara specimen, in regard to which Mr. Pearson hopes to obtain further information.

RECENT observations by Prof. S. O. Mast (*Journ. Exper. Zool.*, vol. ix., No. 2) on the reactions of *Amoeba proteus* to light show that a sudden and sharp increase of light intensity causes retardation or cessation of movement; if the intensity be maintained constant for a few moments, the movements of the Amœba begin again. A gradual increase in intensity produces no response, so that the reaction to light depends primarily on the rate of change of intensity. Blue rays (430–490 $\mu\mu$) are nearly as efficient as white light in producing reactions, but violet, green, yellow, and red produce only slight effects. The author suggests that, as other organisms respond most definitely to light of other colours—violet, green, yellow, or red—it is probable that different photo-chemical changes are associated with the reactions to light in different organisms. Prof. Mast has given, in the *Psychological Bulletin*, vol. vii., pp. 267–80, an abstract of literature, of the year 1909, on the behaviour of lower organisms, including a summary of the discussion on the subject of tropisms by Messrs. Bohn, Loeb, Jennings, and Darwin at the International Congress of Psychology, held at Geneva.

THE *Zentralblatt für Physiologie* (Bd. xxiv., No. 17) is almost entirely occupied by an excellent summary, extending over fifty-two closely printed pages, of the numerous papers read before the eighth International Congress of Physiologists, held at Vienna on September 27–30 last. The number also contains three short original contributions. In the first of these Fr. Kutscher gives the results of his examination of the aqueous extract of mushrooms, which he found to contain arginin, cholin, betain, and a hitherto unknown base, the formula of which is similar to that of histidin, with the addition of three methyl groups; but the organic bases form only a very small portion of the extract, the physiological action of which depends on other substances present. T. Kinoshita concludes, after a series of analyses, that normal, fresh human urine contains only a trace of trimethylamine, but, on standing, this substance is formed during some fermentative process. E. Berlin describes a new synthesis of γ-homocholin, starting from β-aminopropylalcohol. Issued with this part of the *Zentralblatt* is a further portion (pp. 177–317) of the Bibliographia Physiologica (third series, vol. v., Nos. 3, 4), prepared by the Concilium Bibliographicum in Zürich, which, with the two preceding parts, contains the titles of papers published in 1909. These are arranged in the usual sections, according to the subjects of which they treat, and there is, at the end, an author-index to the contents of the whole volume.

To the Transactions and Proceedings of the Perthshire Society of Natural Science for 1909–10 (vol. v., part ii.) Mr. R. Dow contributes a life of David Douglas, of Scone, who introduced into Great Britain no fewer than seven species of American conifers, among which *Abietia Douglasi*, although originally discovered in Nutka Sound during Vancouver's voyage round the world, was named in his honour. Douglas was born at Old Scone in 1799, and, after being employed at the Glasgow Botanical Gardens, started in 1824 on a botanical expedition to the banks of the Columbia River and the neighbouring districts. Thence he travelled southwards to California in 1831, and two years later left America for the Sandwich Islands, where he died, as the result of an accident, in 1834. In 1847 a monument was erected to his memory by public subscription in Scone churchyard. Although they were not introduced into Great Britain until considerably later, *Sequoia sempervirens* and *S. gigantea* (the so-called Wellingtonia) were practically discovered by Douglas, the notices of them by Archibald Menzies in 1795 and 1796 being very imperfect.

In the February number of *Petermanns Mitteilungen*, with which *Globus* is now incorporated, Dr. V. Paschinger discusses the results of an investigation of the snowline in different regions. The present article is but a summary, since the full discussion is to be published later, but the main results are here given. The principal determining factor he considers to be temperature, except in regions where the snowfall is exceptionally heavy, when precipitation is more influential climatically. For a certain number of places he has been able to compare the position of the snowline in different years, and finds that generally in the northern hemisphere at the beginning of the 'seventies it occupied a position of minimum altitude, and has reached a maximum level since 1890.

The results of Dr. K. Sapper's journey in the island of South Mecklenburg of the Bismarck Archipelago, undertaken in 1908 for the German Colonial Office, are published in the third Erganzungsheft of the *Mitteilungen aus den deutschen Schutzgebieten*. The topography and physical conditions of the island and others near it were principally studied, but the climate, the densely wooded nature of the region, and the short time available only admitted of a rapid reconnaissance, while the botany and zoology could be scarcely attempted. Using the charts of the German Admiralty as a basis, compass and aneroid were used to determine the land features, which are given in orographically coloured maps; but these, for the above reasons, can only represent the general relief of the island without claiming accuracy of detail. Geological investigation was rendered difficult by the vegetation, and gravel in the stream-beds furnished specimens of rocks which were not otherwise met with. Oligocene limestones and glauconitic sandstones were found; but most of the sedimentary rocks, consisting of sandstones, limestones, tuffs, and clays, are considered to be Pleistocene. Diorite, syenite, gabbro, and granite were met with, but a far larger area is occupied by the younger eruptive rocks, principally andesite.

In Nature, vol. lxxix., p. 234, M. Paul Macey's descriptions of subterranean waterways in Indo-China were referred to. He now supplements his paper in *Spelunca* by an illustrated account of the "Tunnels naturels du Laos" in *La Nature*, 1911, p. 102. We are surprised that he gives no reference to his previous paper, where his adventures and explorations underground were described so cheerfully.

Herr H. Habenicht, of Gotha, has circulated a pamphlet, "als Manuskript gedruckt," entitled "Spuren der Eiszeiten in Norddeutschland und Versuch ihrer Deutung" (Gotha: Andreas Perthes, 1910). It is accompanied by an excellent map in colours. The author directs attention to the absence of true terminal moraines along the margin of the northern glacial drift in its most southerly extension. The deposits in this region, unlike such moraines, show curved forms that are convex towards the north, while their terminations reach down into the valleys that notch the Thüringian, Saxon, and Sudetic border. The author believes that the facts require the occurrence of a great flood between two ice-ages, whereby the deposits of the older ice-age were swept into their present positions against the southern hills. An interglacial diluvium was thus deposited; but an older one also exists. Loess was formed in pre-glacial times during an epoch of continental elevation, and of consequent dryness through remoteness from the sea. A catastrophic falling in of the surface swept the sea water over this, and led to the formation of an old diluvium. Then followed the first ice-invasion, a second uplift and a steppe epoch, and a second general sinking and "Sturmflut des Weltmeeres" The consequent rains brought on the second ice-age, when the glaciers only reached the Baltic region. The mixture of the remains of Arctic and tropical or steppe animals is attributed to flood-action. It is clear that Buckland's early views have lived on, in spite of the conversion of their author.

In a paper contributed to the Spanish Institute of Civil Engineers (Barcelona: Guinart et Pujolar), Dr. Paulino Castells Vidal describes an ingenious balance for finding the real roots of an algebraic or similar equation. This apparatus consists of a horizontal shaft on which are attached cams in the form of equiangular spirals or similar curves, from which may be suspended weights representing the coefficients of powers of x in an algebraic equation; on the other hand, the arms of the levers formed by the cams are for different values of the angular coordinate proportional to the values of 1, x, x^2, for different values of x. Consequently, when the apparatus has come into a position of equilibrium, the pointer attached to the shaft at once gives a real root of an algebraic equation the coefficients of which are the weights of the loads suspended from the cams.

We have received the reprint of a paper, by Mr. Cyril F. Lan-Davis, read before the Optical Society last December, and reprinted from *The Optician and Photographic Trade Journal*, dealing with the theory of the iris diaphragm. Hitherto these useful optical accessories have been mainly designed by trial, with the result that in many cases it has been stated to be impossible to give sufficiently large ranges of aperture for the requirements of modern lenses and their fittings. The author now shows how the problem can be treated by the methods of elementary geometry, and the conditions for maximum range of aperture, as well as for other important requisites, such as a long scale with equal divisions, can be made the subjects of exact calculation. Neglecting the dimensions of the pins which carry the leaves, it is shown that the maximum aperture obtainable is 0·823 of the diameter of the diaphragm itself, and that for this twenty-five leaves are required. This is a good example of a problem where a little mathematics may save a great deal of random experimenting.

Intending purchasers of microscopes and microscopic apparatus will be well advised to consult the list issued by Messrs. R. Winkel, of Göttingen, obtainable from their London agents, Messrs. H. F. Angus and Co., 83 Wigmore Street. Attention is specially directed to the microscope stand No. 1*d*, the fluoride objectives that originated in Göttingen, and an excellent series of complanatic eyepieces giving a particularly flat field. The general workmanship and finish compare favourably with those of other leading makers. The object marker is a new piece of apparatus similar in shape to an objective, and in place of which it is inserted, for marking a circle round any desired spot on a slide. The type supplied for marking covered objects is provided with a diamond point set in a mount that can be rotated.

In the September (1910) number of the Journal of the Franklin Institute, Philadelphia, Mr. J. H. Dellinger, of the Bureau of Standards, made a preliminary announcement of an interesting relation he had discovered between the electrical resistivity, the coefficient of increase of the resistivity with temperature, and the density of specimens of copper of all makes submitted to the bureau for test. According to Mr. Dellinger, the product of the three quantities mentioned is constant for all specimens of copper

at 20° C. This result, according to a paper by Dr. S. Lindeck, of the Reichsanstalt, which appears in the January number of the *Verhandlungen der Deutschen Physikalischen Gesellschaft*, is confirmed and extended to very impure coppers and to aluminium and iron by the tests made at the Reichsanstalt during the past five years.

ACCORDING to notices to hand from the Société française de Physique, the *Journal de Physique* is in future to be published by the society, and the three-monthly *Bulletin des Séances* is no longer to be issued. The increased cost is to be met by an increase of the subscriptions to 25 francs for resident and 20 francs for non-resident members. The first issue of the *Journal de Physique* under the new conditions, which appeared early in January, contains a *résumé* by Messrs. Cotton and Mouton of their work on the magnetic double refraction of pure liquids, to which we referred in these columns in November last. The abstracts of papers which have appeared in other periodicals occupy about twenty pages, and seem thoroughly good, but as they nearly all relate to papers published in the early months of 1909, it is evident that much requires to be done before the journal can claim that it is placing the present state of the various branches of physical science before its readers.

WITH reference to an offer recently made to the Calcutta University by the Hon. the Mahárája of Cassimbazar of 20,000 rupees, for the purpose of editing and translating Sanskrit texts dealing with astronomy and mathematics, Dr. G. Thibaut stated, at the meeting of the Asiatic Society of Bengal on February 1, that he will shortly explain the present state of knowledge of Indian astronomy and mathematics, and point out what remains to be done in the way of publishing and translating. In this connection he will deal shortly with the following points:—the successive stages of the development of astronomy and mathematics in India; the characteristic features of each stage; the question whether the astronomical and mathematical knowledge possessed by the ancient Hindus originated in India or was borrowed in part or in its entirety from some other nations (Greeks or Babylonians); the use which has been made of certain data of an astronomical nature met with in the *Veda*, for determining the age of the *Veda* or of Indo-Aryan civilisation.

COMMENTING on the *Waratah* wreck inquiry, *Engineering* for February 24 states that the most important point which emerges from the finding of the Court appointed by the Board of Trade is the recommendation that a committee of experts should be appointed to arrive at some conclusion concerning the minimum stability requirements of different types of vessels at sea. Curves showing these requirements might be utilised for preparing rules for the guidance of shipowners in the stowage of cargo in each ship with greater precision than is now possible. Our contemporary states that it has been the practice with experienced builders, among whom should be classed the builders of the *Waratah*, to supply owners with full information regarding the stability of the ship under all conditions of loading, and with instructions as to the disposition of the ballast, in order to ensure the continuance of satisfactory conditions. But there is no certainty as to whether or not these conditions are scrupulously fulfilled by the officers responsible for the ship. The proposal to institute a committee for the formulation of rules is satisfactory in itself, but something more is required in order to ensure that the rules will be carried out most carefully.

A CONTRIBUTION from the Jefferson Physical Laboratory, Harvard University, appears in the Proceedings of the American Academy of Arts and Sciences for January, giving an account of some experiments on the action of mercury on steel at high pressures. Amagat in 1893 described a case in which mercury was forced by a pressure of 3000 atmospheres in a fine spray through 8 cm. of cast steel, in which no flaw could be afterwards detected with the microscope. In the experiments now described, twelve similar test cylinders were cut from a bar of Krupp's special chrome nickel steel. Six of these were tested under mercury pressure, and the others were tested with a glycerin and water mixture, with ether, and also CS_2. Five of the cylinders tested with mercury burst at pressures from 3000 to 4750 kilograms per square cm.; one burst at 10,250 kilograms per square cm. None of the cylinders tested with other fluids burst, even under pressures of 24,000 kilograms per square cm. Soft steel cylinders show this effect hardly at all, owing to the interference of the lower yield point of the material. Examination of the fracture seems to establish the fact that the lower strength of hard steel cylinders under mercury pressure is owing to amalgamation. Amalgamation once started, it spreads with great rapidity throughout the metal. Two causes hasten the rapidity of the action: one is the natural affinity of mercury and steel, the other is the straining action of the pressure, tending to open the pores. The latter view is strongly supported by the fact that, in the fractures, amalgamation was observed to be most rapid in the direction in which the pores were most distended.

OUR ASTRONOMICAL COLUMN.

ASTRONOMICAL OCCURRENCES FOR MARCH:—

March 2. 5h. 58m. Venus in conjunction with the Moon (Venus 2° 20′ N.).
4. 10h. 22m. Saturn in conjunction with the Moon (Saturn 1° 39′ S.).
9. 17h. 23m. Neptune in conjunction with the Moon (Neptune 5° 22′ S.).
10. 21h. 40m. Mars in conjunction with Uranus (Mars, 0° 23′ S.).
18. 14h. 8m. Jupiter in conjunction with the Moon (Jupiter 1° 47′ N.).
20. 1h. 0m. Mercury in superior conjunction with the Sun.
21. 5h. 45m. Sun enters sign of Aries. Spring equinox.
24. 16h. 49m. Uranus in conjunction with the Moon (Uranus 4° 39′ N.).
25. 12h. 3m. Mars in conjunction with the Moon (Mars 4° 15′ N.).
28. 17h. 50m. Venus in conjunction with Saturn (Venus 2° 25′ N.).
30. 12h. Neptune stationary.
,, 18h. 51m. Mercury in conjunction with the Moon (Mercury 2° 22′ N.).
31. 23h. 15m. Saturn in conjunction with the Moon (Saturn 1° 58′ S.).

A REMARKABLE METEOR.—Mr. W. F. Denning writes:—"On February 19, at 9h. 24m., a brilliant meteor was seen by Mr. and Mrs. Wilson from Reigate, Surrey, and by Mr. Peecock from Stowmarket. The object was a very exceptional one for its slowness of flight. At Stowmarket the meteor is described as having a bright reddish-yellow head, with a glowing tail about 15 degrees long streaming behind. It was traced from low in the south-west to low in the north-east. It was in full view for thirty seconds or more.

"At Reigate only the last 27 degrees were observed from just north of Coma Berenices to close to Arcturus. It was the slowest meteor ever witnessed by the observers, who counted sixty, equal to about thirty seconds, while it descended. It showed a bright head, and a yellow tail marked its path.

"The object probably had its radiant south of Orion, and its course lay from about the English Channel, south of Devon, to the coast of Holland. The whole of the path traversed must have been about 520 miles, but the heights cannot be exactly determined from the materials. Another good description of the apparent flight would be very valuable. The night was clear, and many persons in the south-eastern counties must have had a fine view of the phenomenon."

THE PHOTOGRAPHIC SPECTRUM OF NOVA LACERTÆ.—In No. 4473 of the *Astronomische Nachrichten* Dr. Max Wolf reproduces and describes the photograph of the spectrum of Nova Lacertæ which he took with the Zeiss two-prism spectrograph (exposure 90m.) on January 13. At first glance the spectrum consists of seven broad bright bands, of which six are accounted for by the hydrogen lines $H\beta$–$H\eta$; the seventh has a wave-length of about 463 $\mu\mu$. The nova spectrum declines abruptly in intensity at about λ 360, not extending nearly so far into the ultra-violet as do the spectra of the Orion stars. The order of brightness of the broad bands is $H\gamma$, $H\delta$, 463, $H\epsilon$, $H\beta$, $H\zeta$, $H\eta$. Dr. Wolf gives the wave-length measures of the different parts of each band, and also finds other faint bands having their centres at the wave-lengths 451·3, 447·4, 443·4, and 405·8; three other broad, faint bands have their maxima at $\lambda\lambda$ 427·3, 425·6, and 422·9.

RECENT OBSERVATION OF HALLEY'S COMET.—To *The Observatory* (No. 432) Prof. Barnard sends the following observation of Halley's comet on January 8, at 21h. 30m. 56s. G.M.T.:—R.A. = 11h. 47m. 16·65s., apparent dec. 18° 24′ 44·3″ S. The comet was 32·8″ diameter, round, and slightly condensed, but had no nucleus. With the 40-inch refractor, its magnitude was estimated to be 13 or 14. Prof. Barnard hopes to be able to follow the comet for the greater part of the present year, and this will provide an enormous arc, over which the comet has been observed during the present return; the determination of its path during this revolution will thus be considerably simplified. In April next the comet will be as far from the sun as is Jupiter.

SEARCH-EPHEMERIDES FOR WESTPHAL'S COMET (1852 IV.).—In No. 4475 of the *Astronomische Nachrichten* Herr A. Hnatek publishes three search-ephemerides for Westphal's comet, which may be found during the coming spring or summer. The three ephemerides are based on the assumptions that the period of the comet may be sixty, sixty-one, or sixty-two years respectively, and each covers the period April 10 to September 7. The rediscovery is doubtful, however, for the calculated magnitudes lie between 10·3 (August 28, 1911) and 13·4.

OBSERVATIONS OF THE ZODIACAL LIGHT AND THE GEGENSCHEIN.—Herr Banachiewicz describes a brilliant apparition of the zodiacal light, seen at Kasan on January 26–27, in No. 4474 of the *Astronomische Nachrichten*. The light extended to Saturn, and the middle of its pyramidal form passed over the stars δ, ϵ, and ζ Piscium. As compared with the Milky Way, the light appeared of a slightly reddish hue, and, so far as the two phenomena can be compared for brightness, was about equally bright.

Observations of the counterglow, or gegenschein, were made by Mr. Innes, Mr. and Mrs. Wood, and Mr. Worssell at the Transvaal Observatory during September and October, 1910, and are published, with sketches, in No. 5 of the Circular. Mr. Innes reports that on September 24, 25, and 26 the counterglow was, and had been, remarkably distinct, lying along the ecliptic as a lens-shaped mass about 10° broad and about 90° long; in spite of the sky-illumination from electric lights and veld fires, visitors were able to see the phenomenon immediately their attention was directed to it. Mr. Worssell gives its approximate limits on October 4 at 9h. 40m. (G.M.T.) as N. +17·5°, S. −4·5°, preceding, 0h. 5m. and following 1h. 20m., thus making the position of the centre R.A. 0h. 32m., dec. $+5\frac{1}{2}$°.

THE MURNPEOWIE METEORITE.—The annual report of the South Australian School of Mines for 1909 contains a very interesting description of the iron meteorite discovered in August of that year. The discovery was made by some boundary-fence repairers working near Murnpeowie, Lat. S. 29° 35′ L. and Long. 139° 54′. Mr. L. Laybourne Smith, the curator of the museum, says the country at this place is flat and devoid of stones. The object is a siderite weighing 2520lb., its greatest height 35 inches. The chemical composition has not been determined. Mr. Smith is making inquiries with a view to finding the date of the fall. "Australian bushmen are very observant, and this isolated 'rock' would not have been overlooked in a position less than half a mile from where the fencers were working. The holes also would fill with sand in a few years. It is probable, therefore, that the Murnpeowie meteorite is a recent arrival."

INTERNATIONAL HYGIENE EXHIBITION, DRESDEN, 1911.

FOR some months past very conflicting statements as to the attitude of the Government towards the International Hygiene Exhibition to be held in Dresden have been made, but we are now assured that the President of the Board of Trade has given it his blessing, and that some of those who have hitherto held aloof, owing to some misunderstanding, have expressed their approval of the movement. It is to be hoped, therefore, that Great Britain will be properly represented in what promises to be one of the most important scientific exhibitions and congresses of modern times. This exhibition is not merely for the advertising of trade products, nor is it intended that it should compete in any way with such trade exhibitions as, for example, that to be held at Turin. Rather is it to be a collection of apparatus and appliances, so arranged and classified that experts or others interested in matters pertaining to hygiene may study, compare, and contrast the most modern and best hygienic contrivances.

Our German cousins, with their genius for organisation and attention to detail, have spared neither trouble nor expense in laying solid foundations, and it now rests with other countries to assist in the building of an adequate superstructure. Great Britain can ill afford to be behind in a race in which, hitherto, her lead has been preeminent; and although she must do voluntarily, through individuals and private organisations, what by other countries is done by the State, it is to be hoped that now all misunderstanding has been cleared away a united effort will be made, not only to raise the rest of the necessary funds, but to send sufficiently imposing exhibits.

Some idea of the thoroughness of the work that is being done may be gathered from the fact that a "News Bureau," from which is issued what may be called a small newspaper—*Hygieia*, has been formed in connection with the exhibition. Of this leaflet, Nos. 16, 18, and 19, all of them published in January of this year, may here be referred to. The first deals with the department of "statistics," and not only affords an indication as to the objects of the promoters of the exhibition, but serves as a guide to would-be exhibitors as to what is most likely to be of use and interest to the "public" whom this exhibition is expected to attract. We are told that the collection of statistics brought together by the German Government has cost something like 350,000*l.*, that games and their influence on health will be illustrated, and that the various implements employed in carrying on these games will be fully set forth. The hygiene of civilised life will naturally receive most attention, but the method of life of savage tribes will also be demonstrated—dwellings, food, mode of life, and the like, of bushmen, Australian aborigines, primitive Indians, North American Indians, all being illustrated. One of the leaflets is devoted almost entirely to milk, under such headings as hygiene of milk; exhibits of apparatus and methods for the bacteriological investigation of milk; models, drawings, and photographs to show the dangers arising from dirty milk; the proper treatment of milk practicable even in small dairies; methods of sterilisation and milk inspection; and the hygiene of butter and cheese. Hygienic cowhouses and fittings, and the best methods of keeping cattle in dairies, and so on.

Another leaflet, No. 19, deals with subjects very different in character—the action of light and special forms of light, such as the ultra-violet rays, the action of radium, and radio-active substances; and then darts off suddenly into an entirely new region, where exhibits and statistics con-

cerning sick clubs, insurance against illness, and many of those other schemes promoted by the German Government, the importance of which is now being so fully realised in other parts of the world, are to be on view.

It is to be hoped that now the matter has been taken up, those interested in British sanitary science and the scientific aspects of hygiene generally, will spare no effort to make the British exhibit, in part at least, worthy of those great leaders of sanitary science who, shortly after the middle of the last century, did so much, not only for Great Britain, but also for other civilised countries.

THE RUSTING OF IRON.

THE problem of the atmospheric corrosion of metals is a very old one. So long ago as 1769, only three years after Cavendish had demonstrated the solubility of chalk and magnesia in water charged with "fixed air" or carbonic anhydride, it was shown by T. Lane, an apothecary of the City of London, that "water impregnated with fixed air will dissolve a considerable quantity of iron, and thereby become a strong chalybeate" (Priestley, "Experiments on Air," 1772). Lane records (Phil. Trans., 1869, l., 218) that "the clear water . . . decanted from the filings and ochrous sediment . . ., being exposed to the open air, presently threw up a party-coloured pellicle, and deposited a yellowish sediment."

In this way the foundations were laid for the theory of rusting put forward in 1888 by Crum Brown, according to which the action consists essentially in the dissolution of iron by carbonic acid, and subsequent precipitation from the solution of ferrous bicarbonate of ferric hydroxide formed by the interaction of the ferrous salt with atmospheric oxygen; the separation of the rust is accompanied by the liberation of the carbonic acid, which is thus set free to attack a further quantity of iron.

The correctness of Crum Brown's theory was confirmed by Moody's observation (Trans. Chem. Soc., 1906, lxxxix., 720) that iron which had been cleaned with chromic acid could be kept for long periods in contact with water and air in a glass tube from which all traces of carbonic acid were carefully excluded. Friend (Proc. Chem. Soc., 1910, xxvi., 179) has confirmed this observation by condensing water distilled from an alkali upon an iron tube cooled by circulating water.

In a paper which has recently appeared in the Journal of the Chemical Society, Messrs. Lambert and Thomson have arrived at conclusions differing somewhat from those of Moody and Friend. By electrolysing ferric chloride between electrodes of pure iridium foil, a specimen of iron was obtained which gave a crystalline nitrate entirely free from the violet colour which usually characterises this salt and ordinary ferric alum; the nitrate was transferred to an iridium boat, ignited, and reduced in a stream of hydrogen in a silica tube at 1000°. The metal thus obtained (which appears to have been so pure as to be acid-proof, like the redistilled zinc prepared some years ago in Sir William Ramsay's laboratory) was found to be unacted on by purified oxygen and purified water, but when platinum vessels were used in preparing the iron, the metal was found to be oxidised in the course of two or three hours, and a similar result was observed in the case of commercial iron, whether it was cleaned with chromic acid or not.

The different results thus obtained may very possibly be attributed to a difference in the vessels in which the iron was exposed to the action of water and oxygen. The dominant factor in promoting the atmospheric corrosion of iron is undoubtedly carbonic acid, but there is no reason to suppose that the part of the carbonic acid might not be played by any other acid strong enough to act upon the iron, though weak enough to be liberated by oxidation from the ferrous to the ferric state. Silicic acid, the immediate homologue of carbonic acid in the periodic classification of the elements, might very possibly be capable of producing a like effect, and, if so, the use of silica tubes would be likely to promote rusting to a far larger extent than tubes made of glass. The use of silica tubes by Messrs. Lambert and Thomson in an experiment in which one of the main objects was to eliminate acid impurities is a change of which the advantages are very questionable. The soluble (alkaline) matter dissolved out from ordinary glass does not suffice under normal conditions to prevent rusting from taking place in glass vessels, but it is noteworthy that under the conditions of Moody's experiments contact with the actual (acid?) surface of the glass was sufficient to cause the metal to rust, whilst Friend has recorded a similar effect produced by particles of slag embedded in the iron. T. M. L.

ECONOMIC GEOLOGY IN THE UNITED STATES.[1]

THE three bulletins referred to below have been issued by the United States Geological Survey, which, at all times keenly alive to the importance of economic geology to the nation, has of late years been paying particular attention to the study of the mineral resources of the United States. The two first bulletins give an elaborate and detailed account of the geology of one of the most important oil-producing regions of central California. Very little accurate geological work had been done here previously, so that the present bulletins form a useful contribution to general stratigraphical geology as well as to the special geology of oil-bearing regions. There is nothing that calls for particular notice in these bulletins; the oil appears to occur in strata of the customary type of Eocene, Lower and Middle Miocene age. Both reports are elaborate and full of detail, and the report on the Coolinga district is noteworthy for the amount of palæontological information that it contains and for the admirable manner in which some of the fossils referred to have been illustrated in the accompanying plates.

The third of these bulletins deals with an entirely different subject, namely, the methods recently introduced by the United States Government for the purpose of placing its system of purchasing its coal supplies upon a scientific basis. The method is roughly as follows:—For each coal the moisture, ash, and calorific value (expressed in British thermal units) are determined upon samples taken with all due precautions. The bids of the various samples are sent in on official sealed forms. In order to compare these, all the tenders are reduced to the same ash value by selecting as standard the coal containing the lowest percentage of ash; for each 1 per cent. of ash above this figure, 2 cents per ton is added to the tender price. From this price thus adjusted, and from the calorific power as determined, the cost per 1,000,000 B.T.U. is calculated for each coal offered, and as a general rule the contract is awarded to the lowest cost as thus ascertained. As the heat value of the coal is determined upon the coal as received, there is no necessity to determine the percentage of moisture that it contains. When a tender has been awarded to a contractor, he is expected to maintain the quality of the coal delivered at approximately the same standard as that upon which the contract was awarded. For this purpose careful samples are taken from each delivery; when the samples have been drawn, payment of 90 per cent. of the amount of the account is made forthwith, the balance being kept in hand until the samples are reported upon. The price is corrected for variation in calorific power, by multiplying by the number of B.T.U. in the sample and dividing by the number of B.T.U. upon which the contract was based. Similarly for each 1 per cent. less of ash in the sample of the coal delivered, a premium of 2 cents per ton is paid, and for each 1 per cent. of ash more a deduction is made in accordance with a published schedule, an increase up to 2 per cent. of ash not being, however, penalised. Of course the contract note contains clauses under which a delivery containing an excessive amount of ash, dust, or sulphur may be entirely rejected.

It will be seen that this system of coal purchasing is novel, and interesting to a wider public than that directly concerned with the supply of coal to the various departments of the United States Government. H. L.

THE AFFINITIES OF SCHIZOTRYPANUM.

IN a recent number of the *Archiv für Protistenkunde* (vol. xx., p. 361), Dr. M. Hartmann makes an important addition to our knowledge of *Schizotrypanum cruzi*, the trypanosome of human beings discovered by Chagas in Brazil (see NATURE, August 4, 1910). Chagas described a process of multiple fission ("schizogony"), taking place in the lung capillaries, of forms not enclosed in cells (NATURE, *l.c.*, p. 143, Fig. 2, *b–e*). In addition to this type of multiplication, Hartmann finds another process of schizogony within hypertrophied endothelial cells of the lung, as a result of which the cell contains some twenty or more small, pear-shaped organisms, each with a distinct kinetonucleus and trophonucleus, but no flagellum. The chief interest of this discovery lies in the very great resemblance of these intracellular forms of Schizotrypanum to those of *Leishmania donovani*, the parasite of Kala Azar; in fact, anyone, looking at the figure given by Hartmann, might suppose that it represented a preparation of Leishmania. Similar forms are stated to have been found in the heart-musculature and brain of human beings that have died from "Schizotrypanosomiasis" (*sic*), *sit venia verbo!*

In view of the resemblance, in certain phases, between Schizotrypanum and Leishmania made known by Hartmann, attention may be directed to some remarks by Donovan, one of the discoverers of the parasite of Kala Azar, in the "Annual Report and Statistics of the Government General Hospital, Madras," for the year 1908 (published 1909), p. 31. Donovan casts doubt on the view advanced originally by Rogers, and further supported by Patton, that the parasite of Kala Azar is transmitted by the bed-bug; and gives reasons for believing that another bug, *Conorhinus rubrofasciatus*, is the insect which propagates the disease. It would be remarkable if both Leishmania and Schizotrypanum proved to be transmitted by species of the genus Conorhinus, the one in India, the other in Brazil. The etiology of Kala Azar is a problem which calls urgently for investigation.

E. A. M.

THE ORGANISATION OF TECHNICAL EDUCATION AND RESEARCH.[1]

VERY few words of mine are needed to emphasise the interest and the importance of this annually recurring ceremonial at which the varied educational work of the City and Guilds Institute receives recognition, well-merited recognition, from successive Lord Mayors.

We gather from the brief *résumé* of the work which has been read by Sir J. Watney that the various agencies combined under the control of the institute continue to flourish, the students increase in number, their work rises in quality, and the importance of the institution grows greater year by year.

The City and Guilds Central Technical College completed its twenty-fifth session in July, and now has at work 412 students. In the twenty-five years, 1512 students have taken the complete course and 1066 have been awarded the diploma. Out of 306 internal degrees conferred in the faculty of engineering in London University, 157 have been obtained by students of the college; and the percentage in honours has been a high one, 56 per cent. first class, 42 per cent. pass.

The year has been marked in that the relations with the Imperial Technical College have been made definite by the appointment of a delegacy, under the immediate control of which the City and Guilds College is placed, and which contains representatives of the Imperial College, the Institute, and the Goldsmiths' Company. The delegacy, I am informed, held their first meeting last month.

I will not attempt to review in like manner the year's results for the other branches of the institute. Numbers of young men—some of them not so young now—owe their success in life to the training received at the Finsbury Technical College from the inspiring teaching of its accomplished head, Prof. S. P. Thompson, and his able staff; and here I should like to thank Prof. Thompson for his recent brilliant addition to our scientific biographies. Had he done nothing else, and this is far from being the case, his life of Kelvin would have left future generations deep in his debt.

I know less, perhaps, of the other work of the institute, but I know enough to be grateful to the committee and its officers for the large contribution to the advance of knowledge they have made by their efforts in the past.

The choice of a subject for an address of this kind is not quite easy, and yet it ought not to be very difficult for a man whose life is now bound up with the business of science to find a theme on which to speak to an audience in this centre of industry and commerce—the connection of science and industry is an obvious, perhaps even a hackneyed, one. Nevertheless, I am going to trespass on your patience with some aspects of the question as they appear to me.

Not many years ago it would have been said that the connection was a slight one. Science dwelt in a realm apart from industry and commerce; her votaries were men who sought the truth without a thought of the gain the search might bring to humanity, or the wealth it might discover for the seeker.

It was enough for them to arrive at some new law, to roll back a little space the veil that shrouds the mysteries of Nature and to penetrate her shrine. Long may there be such men; the humbler students of science, those who try to interpret her teachings for the good of men, could advance but little without the torch of truth carried by these their leaders. But it is realised now that there are many ways in which science can further industry. Let us look at two of these.

It is sometimes said our German cousins are more scientific than ourselves, and that this is the reason of their great material progress during the past fifty years. In a sense this is true; not that they have made greater discoveries or have contributed more to the sum of human knowledge, but they did realise at an earlier date than we the value of science as a factor in industrial and commercial progress. They showed their appreciation of its importance by the establishment, in the first place, of technical colleges and universities where students could be trained to apply science to the needs of daily life, and in the second of institutions like the Reichsanstalt and the Versuchsanstalt, where researches on matters bearing on the application of science to industry could be carried out on a fitting scale.

The colleges and universities which in the past twenty-five years have grown up in our cities show that we have begun to appreciate the need and to make some notable endeavours to supply it. For the success of these endeavours, no small debt is due to those great City Guilds which, with well-judged munificence, have devoted such large funds to the work of education, not only here in London, but also in the ancient universities and in many other parts of the country.

This gathering to-night, with its long list of prizes and awards, is a speaking testimony to the value of their work in London. The wise leaders of the City Guilds realised that by the work of education they could best advance the welfare of our country and carry on under present conditions the task which previously they performed by means of the apprenticeship system.

Let us look into this educational work in its modern form. It received a notable impulse a few years ago by the establishment of the Imperial College of Science and Technology. That college was founded with a very definite purpose—to afford to English students the opportunity for the highest study and research in any branch of science bearing on industry. Two methods at least were open to the founders, and of these they chose the more difficult. It is our English plan to let our old institutions develop gradually, so as to meet new needs. The committee responsible for founding the Imperial College might have established something quite new; they decided rather to combine three great agencies existing at South Kensington into one, thus coordinating work already in progress, while maintaining the individuality of the constituent institutions. The Royal College of Science, the Royal School of Mines, and the City and Guilds Technical College still exist, but, combined as they are under one governing body of the Imperial College, their

[1] Address delivered at the prize distribution of the City and Guilds of London Institute on February 17, by Dr. R. T. Glazebrook, F.R.S.

influence on education and on progress, great as it has been in the past, must be multiplied manifold.

Time is necessary to solve the many problems that arise, but a visit to South Kensington, where, by the generosity of Messrs. Wernher, Beit and Co., and the trustees of the Bessemer fund, splendid new buildings are rising rapidly for the Royal School of Mines, and by the munificence of the Goldsmiths' Company the engineering laboratories of the central institution are being so greatly enlarged, is enough to show some of the first-fruits of the work.

The method which has been adopted for controlling the work of the Central College by means of a delegacy representing the Imperial College, the City and Guilds Institute, and the Goldsmiths' Company, is full of promise, and the path whereby the whole can develop into the great institution planned by its founders seems clear.

Much is still necessary before that development can be complete. In the first place, we must encourage research. The Central Technical College has a splendid record among its professors—Henrici, Unwin, Ayrton, Armstrong. Nor will the work of the younger men—Dalby and Mather—be less distinguished in the future. Still, more remains to be done in the way of post-graduate study and students' research. I do not overlook the notable efforts made lately in connection with the railway engineering course, but I would urge those in whose hands control lies so to organise the teaching that men, professors, or students who have the power to carry on research, should be free to use it. You cannot successfully command a professor to make discoveries. You can arrange his surroundings so that the power that is in him should have full opportunities of action.

Secondly, we must not attempt in the Imperial College to do elementary work which can be done equally well elsewhere. The Central Technical College has always done rightly in selecting its students with care. Its success, and the fact that the students now number as many as the college can hold, increase its power of selection; the conditions of entrance may be raised gradually; they are still very low compared with the great German technical schools; and thus the whole character of the work may be improved.

Thirdly, the Imperial College must not remain isolated. The agencies at work in London applying science to the wants of industry, not merely teaching the rudiments, but advancing the boundaries between the known and unknown, are numerous; they include the University Colleges, with their distinguished professors and their large classes of students; the polytechnics and technical schools, where, day and night, educational work of the highest value is being eagerly pursued.

Is it impossible to conceive some scheme by which the labours of all these agencies for technical instruction should be coordinated and linked up with the work of the Imperial College as a centre, to which, to repeat what I said in an address I delivered to the Association of Technical Institutions, students only of proved capacity were admitted, where the staff and students were free to conduct original investigations, and through these to learn new truths, where scholars and prizemen from the various technical institutions of London were collected, and where the teachers in the polytechnics and other colleges were freely welcomed to carry out their researches and to advance learning?

In close connection with this there should be a number of colleges organised so as to provide teaching for the less advanced stages of the course, selected with due regard to geographical conditions.

Beyond these would come those polytechnics which were engaged chiefly in evening classes for the worker, each, if possible, with one special department organised so as to provide teaching and means for research of an advanced character, linked up to the central institution, the Imperial College, in such a way that the teachers felt a common interest in promoting the welfare of that institution, and turned naturally to its professors as their leaders in the search for truth.

There is one essential more. This group of institutions —the Imperial Technical College and its associated colleges—must possess the power itself of granting degrees in technological science to its students who have gone through its course and passed the proper tests without reference to any external academic body. To secure this may be difficult, but it must be done. In Germany it was recognised some years ago that the degree courses of the older universities did not afford the student of technology the training he required, and new universities —technological universities they are called, though the phrase may be a misnomer—have been established in many of the great centres of industry.

Here in England, outside London and the old universities, our course has been different. The new universities in Manchester, Liverpool, Birmingham, and elsewhere, have each a faculty of technology along with those of arts and science, law and medicine, and their constitution allows them to do this with success, for in no case is the control in the hands of an academic body—an unwieldy Senate representative of all and every conflicting interest that can conceivably be brought in. It rests with a compact council, consisting mainly of business men, keen to raise the standard of education in their cities because they realise that on that progress turns.

It may be possible to reorganise London University as an assemblage of faculties, each practically independent in its own sphere, each controlled by its council, a small body of men containing some few representatives of the teaching staff. This council, within the scheme, would be the supreme body of the faculty; subordinate to it would be the general board of studies, representing all the teachers, and the special boards dealing with the various subjects of study in the faculty. Each faculty should award its own degrees and be free to determine, with the lines of the general scheme, the conditions under which those degrees should be granted.

There would need to be advisory committees of representatives of several faculties for work in which more than one faculty was concerned, and a small body, independent of the faculties, to settle disputes which might arise.

Under such a scheme the Imperial College would become the centre of the Technological University for London, and then for the Empire, a body like its governing body, but modified so as to include representatives of the other institutions which would form with it the technological side of the University in London, would become the council of that faculty; the teachers in the various subjects represented in the faculty would form the various special boards of studies, and representatives of these special boards would become the general board of studies of the faculty.

Whether this be a possible scheme or not it is not for me to say, but I would venture to put forward three propositions:—

(1) That a combination of the technological departments of existing institutions and schools into an independent technological faculty is necessary.

(2) That in such a faculty a definite value should be given to technical education in each London school.

(3) That the technological faculty should confer degrees under conditions to be laid down by the faculty.

I am aware I have wandered into debatable ground. I trust I have not erred beyond forgiveness in so doing. The task before Sir Alfred Keogh, the rector of the Imperial College, in bringing to success some scheme such as this is no easy one. It will lighten it immensely if you can assure him that in his task he has your own support and that of the men to whose active help the success of the City and Guilds Institute is so largely due.

You may rest assured that in this way you are assisting in no small degree to render the advances of science available for the promotion of the best interests of our nation, in strengthening our position in the world, and in carrying on that great work of education in which the City Guilds have taken so admirable a share.

But there is another aspect of my subject, the relation of science to industry, for which I have left too little time. A second way in which science may help industry is, as I have said, by the establishment of institutions where scientific questions bearing on industry may be studied.

The National Physical Laboratory is such a place, and when the chairman of the committee invited me to speak

here to-night, he said he wished me to tell you something of the work of the laboratory.

It is a big work, for the subject is big. The laboratory was founded some ten years since as a public institution for standardising and verifying instruments, for testing materials, and for the determination of physical constants.

Its staff now numbers about 140 persons, its expenditure during the past year was more than 28,000*l.*, and towards defraying that expenditure more than 15,000*l.* was received in fees for work done.

During the past eleven years, if we exclude the aëronautical work, 49,000*l.* has been contributed from public funds towards capital expenditure, while 54,000*l.* has been raised from private sources. In the same period, the annual grants from the Treasury for working expenses have been 57,750*l.*, while the receipts from fees, private donations, and subscriptions have come to 105,380*l.*

Instruments of all kinds were examined, among them in 1910 were 27,500 thermometers, 4000 telescopes, 1600 binoculars, electrical apparatus, measuring apparatus, optical appliances, photographic lenses, opticians' testing lenses (these numbered 5000), and taximeters. The value of the instruments sent for test is nearly 1000*l.* for each working day of the year.

Nor is this half of the work. Researches of all kinds of interest to industry and manufactures are in progress. Papers have been communicated to engineering and scientific societies which have aided in the solution of many important technical problems, and investigations are now in progress which will help still further.

The laboratory is controlled by a committee appointed by the Royal Society and representing the great scientific and technical societies, and the general scheme of research is approved by them. But besides these public investigations, each day brings us inquiries from private firms and manufacturers as to matters on which they want our help or our advice.

The home of the laboratory is at Teddington, in Bushy Park, and there, round the old Royal residence, Bushy House, the modern buildings needed for the work are being slowly and painfully raised. For some of these funds have been provided by the Government; others we owe to private generosity to men like Sir Andrew Noble, Sir John Brunner, Mr. Yarrow, who has just built for us an experimental tank for naval research at a cost of 20,000*l.*, Sir Julius Wernher, whose generous gift of 10,000*l.* has rendered it possible to commence the erection of a laboratory for metallurgical research, or to those of the city companies, the Goldsmiths', the Drapers', and others, who have listened to our appeal.

Meanwhile, we live from hand to mouth; the deficit this last year, on a total expenditure of nearly 30,000*l.*, was about 200*l.*, and now we are appealing for funds to build an optical laboratory, a library, and reading room, with other offices for our work.

We shall not appeal, I know, in vain, because Englishmen at last are realising that organised scientific effort is an essential factor in the country's progress; you students who in the various colleges of this institute have learnt something of what science is, what scientific effort can do, in time some of you will become the leaders of industry. See to it, then, that those institutions to the work of which your success is due are made ever more efficient through your generous support.

PROGRESS REPORT OF THE CARNEGIE INSTITUTION OF WASHINGTON.

THE ninth annual report of the Carnegie Institution of Washington, in which the numerous activities of the institution during 1910 are described, is now available. The volume runs to 275 pages, and contains also five well-reproduced plates. As usual, the report includes the articles of incorporation of the institution, its bye-laws, the minutes of the meeting of the Board of Trustees, the report of the president of the institution, that of the executive committee, as well as detailed reports on the numerous investigations and projects of the institution.

The president's report presents in order a review of the work of administration of the institution, a *résumé* of the investigations carried out during the year, and a summary of the publications authorised and issued during the year ending October 31, 1910. The subjoined extracts from the report will serve to illustrate the increasing importance of the research work undertaken under the auspices of the institution.

Work of Administration.

The more noteworthy events in the history of the institution during the past year are the dedication, in December, 1909, of the Administration Building; the inauguration at that time of an annual series of semi-popular lectures explanatory of the researches of the institution; the inauguration on the same occasion of a series of periodical exhibits of the work accomplished by the departments of investigation and the divisions of publication and administration; the successful completion of the first voyage (of 8000 miles) of the non-magnetic ship *Carnegie*, and the beginning of a second cruise, which is expected to require three years, by this novel craft; and the fourth conference of the International Solar Union, held at the Solar Observatory of the institution on Mount Wilson, California, from August 29 to September 4, 1910.

It appears that since its organisation in 1902 upwards of twelve hundred individuals have contributed in one way or another to the promotion of the researches and the publications undertaken by the institution. During each of the past five years about five hundred individuals have thus collaborated. Ten independent departments of research and the divisions of publication and administration, each with its staff and assistants, have been organised and established within the institution itself. In addition to these larger departments of work, numerous special researches, in aid of which upwards of seven hundred grants have been made, have been carried on by research associates and other individual investigators. For the departments of research, two astronomical observatories, five laboratories, and a non-magnetic ship have been built and equipped.

The following list shows the departments of investigation to which the larger grants were made by the trustees, and the amounts allotted from those grants by the executive committee during the year:—

	£
Department of Botanical Research ...	6,946
Department of Experimental Evolution ...	8,194
Department of Economics and Sociology...	2,000
Geophysical Laboratory	10,204
Department of Historical Research ...	4,540
Department of Marine Biology	5,414
Department of Meridian Astrometry ...	7,131
Nutrition Laboratory	5,276
Division of Publications	1,800
Solar Observatory	23,144
Department of Terrestrial Magnetism ...	15,384
	90,032

Résumé of Investigations of the Year.

Work in the ten specially organised departments of research in the institution has gone forward during the year with increasing vigour and with increasing productivity. But while the existing status of departmental affairs is in general highly satisfactory, it appears essential again to direct attention to the fact that with present income and current economic conditions no further expansion of departmental appropriations can be expected. It may be necessary, on the contrary, to curtail research in the departments in order to keep the aggregate expense of the institution within income. It need not follow, however, that this prospective diminution in financial outlay will cause a corresponding diminution of productivity, for work of investigation, like work along other novel lines, is usually most costly in the preliminary stages.

The headquarters of the Department of Botanical Research are located in a desert area where the facts of plant life are exhibited, in general, in their simplest, though often extreme and highly specialised, relations. During the year the director of the department has continued his investigations on the water-balance of succulent plants, on the conditions of vegetable parasitism, on the variability in plant species induced by chemical treatment of their seeds, and on the influences of climate on plant organisms.

In collaboration with Prof. Ellsworth Huntington, the director has begun a general climatological study of the region about Tucson, giving special attention to the factors and effects of the Santa Cruz and Asuncion river systems. Dr. Cannon has given attention especially to his elaborate investigation of the root systems and habits of desert plants. For the purpose of extending the range of his studies in this fundamental subject, he visited the Sahara Desert, and will spend most of the year in that advantageous field for both comparative and direct observations. Dr. Shreve, while occupied with the more general problem of the relation of plants to climate in the United States, has also carried on special investigations of the vital statistics of plants in the vicinity of the desert laboratory, of the vegetation in the Santa Catalina Mountains, and of the physiological characteristics of the lace-fern family of plants. Observations on the phenomena presented in the drying up of Salton Sea, and especially on the influx of vegetation over the bared strands and islands of this slowly retreating body of water, have been continued during the year.

So many converging lines of fruitful research are now being pursued by the Department of Experimental Evolution that it is difficult to summarise fitly its current progress. From the abstract scientific point of view, the most interesting feature of this work is found in the introduction of statistical and other quantitative methods, whereby biology is now passing from the first to the next higher stage in the development of a science. From the more popular points of view, the work in question is of special interest by reason of its bearing on the economics of plant and animal breeding, and by reason of the light it is certain to shed on the laws of human heredity.

The principal steps which have been necessary, and in large degree preliminary in the development of the work of the Geophysical Laboratory, are four in number, namely, provision for correct temperature determinations over the entire range involved in the processes of rock formation; provision for like determinations of the chemical reactions of these processes; provision for precise microscopic, optical, and crystallographic measurements; and provision for the quantitative applications of high pressures to rock masses and rock constituents. In supplying the desiderata just indicated for its own special work, the laboratory has already achieved results of prime importance also to many other fields of physical and chemical science. Thus, two contributions of great import to general physics and chemistry have been brought out during the past year. The first of these is a determinate extension of the scale of temperature measures from about 300° C. to about 1600° C. This is a fitting supplement to the classic work on thermometry begun more than thirty years ago under the auspices of the International Bureau of Weights and Measures. It must take rank, in fact, with the fundamental advances in the technique of thermometry. The other contribution is a determination of the system of compounds which may arise in combinations of the three most important oxides entering into the composition of rocks, namely, silica, lime, and alumina. This system is of special economic interest, since it includes, among many other compounds, the hitherto much studied but baffling Portland cement. The complexity of the investigations required to analyse this system is indicated by the facts that it involves the interaction of fourteen minerals and the formation of sixteen ternary eutectics, or substances the melting points of which are lower than those of the primary constituents.

Two emergencies seriously affecting the Department of Marine Biology, and calling for prompt action, have arisen during the year. One is due partly to the gradual abandonment by the U.S. Navy of the supply depôt and wireless station at Tortugas, where the department's laboratory is situated, thus rendering communication between Key West and the laboratory less certain and frequent than hitherto. The curtailment of this source of aid generously extended by the Navy to the laboratory during the past six years has forced upon the department the necessity of providing better independent transportation than that afforded by its best boat, the *Physalia*. Accordingly, plans and specifications for a 70-foot twin-screw boat were prepared during the summer, and on authorisation by the executive committee, a contract for the construction of this proposed vessel was let, with the expectation that the contract will be completed in July next. The other emergency arises from the damage to the laboratory caused by the hurricane of October 14–18, 1910. The extent of this damage is not definitely known at present, but steps have been taken to get trustworthy details at the earliest practicable date, so that estimates of the expense required to restore the building may be ready for submission to the Board of Trustees before their next meeting. It is gratifying to note that the opportunities afforded for intensive research by the laboratory are so highly appreciated that applications for its privileges are already more numerous than can be granted.

Capital progress has been made during the year in the large and exacting undertaking which the Department of Meridian Astrometry has so successfully started. Work at the observatory in Argentina has gone forward at an unprecedented rate, and with such a degree of thoroughness and completeness as to give assurances that this part of the enterprise will be completed within the next year. While the supplementary observations of the positions of the stars are going forward in the southern hemisphere, arrangements for the final computations of these positions are proceeding at the Dudley Observatory; for the formidable task of observation must be followed by a still more formidable task of computation. Preliminary to the grand catalogue of stellar positions projected by the department, there has been issued by the institution during the past year, as Publication No. 115, a catalogue of 6188 stars for the epoch 1900.

Although the Nutrition Laboratory has been occupied less than two years, and is not yet fully equipped, it has already produced contributions of fundamental importance to our knowledge of the chemistry, physics, physiology, and pathology of nutrition. Its experience, like that of all the laboratories of the institution, affords an impressive demonstration of the productivity attainable by concentrated effort along determinate lines of research. Construction and installation of additional equipment, the prosecution of investigations, and the publication of results have gone forward simultaneously during the year. One new calorimeter has been completed, another partly constructed, and various auxiliary apparatus for use with these and the earlier equipments have been supplied. Similarly, respiration apparatus for men, respiration apparatus for dogs, and many improvements in the calorimeter section of the laboratory have been made. Several pieces of apparatus have been acquired also by purchase abroad, and the efficiency of the machine shop has been improved by the addition of a precision lathe.

The work of the Solar Observatory is now so extensive and so varied that it is somewhat difficult to summarise even in its salient aspects. In addition to the observatory proper, with its four principal telescopes and much auxiliary equipment on Mount Wilson, there are the physical laboratory and the instrument shops at Pasadena, along with special divisions devoted to the work of computations and construction respectively. By way of equipment, several large pieces of apparatus for the new tower telescope, for the 60-inch telescope, and for the 100-inch grinding machine have been made at the shops. The towers for the new 150-foot tower telescope, begun a year ago, are now finished, along with the well, 75 feet deep in the rock below, which forms a part of the telescope tube of this novel instrument, now essentially complete except for its spectroscopic attachments, still under construction at the shops. Some preliminary trials made recently with this instrument indicate that it will fulfil the sanguine expectations entertained in respect to its capacity.

The more striking events of the year in the Department of Terrestrial Magnetism refer, naturally, to the non-magnetic ship *Carnegie*, which was off on her first cruise at the close of the previous fiscal year. She was then at Falmouth, England, where her determinations of the magnetic elements were compared with independent determination made at the permanent magnetic observatory of that port. She proceeded thence, November 9, 1909, to Funchal, Madeira, thence to Hamilton, Bermuda, and thence, under tempestuous conditions which proved her seaworthiness, to Brooklyn, N.Y., where she arrived February 17, 1910. Here she had her copper sheathing applied by the constructors, as required by their contract,

and was overhauled and refitted for a three years' circumnavigation cruise. In all essential respects this vessel has proved more effective than was anticipated. It has been demonstrated that even in rough weather the three magnetic elements may be determined with a precision little short of that attainable in a fixed observatory. Thus she was able to discover on her first cruise errors of unexpected magnitude in the best sailing charts of the north Atlantic, and she is certain to attain at least an equal degree of precision in all future ocean work. By crossings of her own tracks and by connections at all available ports having magnetic observatories, it will be practicable to exclude the possibilities of any important errors in this work. Similarly satisfactory progress has been made also in the land work of the department during the year. The expedition in Africa, from the Cape to Cairo, undertaken by Dr. Beattie and Prof. Morrison as temporary associates, was completed early in the year, a total of 348 stations having been occupied. Mr. Pearson continued work in Turkey in the early part of the year, until relieved by Mr. Sligh, who extended the work to Palestine, Syria, Arabia, Mesopotamia, and the islands of Rhodes and Cyprus. Up to the end of July of this year, these two observers had occupied a total of forty-seven stations. Another observer, Mr. Stewart, left Washington early in June to begin extensive work in South America, proceeding in the launch *El Imán*, provided especially for work along the Amazon and its tributaries. Additional observations are reported also from Canada and from various European countries in which initial determinations or instrumental comparisons have been made.

The publication of twenty-three volumes has been authorised during the year by the executive committee, at a total estimated cost of 7980*l*.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

Cambridge.—Sir George H. Darwin, K.C.B., F.R.S., has been nominated to represent the University at the celebration in September of the secular jubilee of the Royal Frederic University of Christiania.

The special board for medicine report that an examination in psychological medicine and its cognate subjects, if established, could not fail to raise the present standard of efficiency in applicants for asylum posts, and that it would lead to the provision of appropriate courses for the training of those who wish to advance our knowledge of psychiatry. The board accordingly recommends that such an examination be held once in the year, and that a candidate who passes both parts of the examination to the satisfaction of the examiners be entitled to a diploma testifying to his competent knowledge of psychological medicine.

Oxford.—The report lately published of the School of Geography gives evidence of much activity. It mentions with regret the resignation of Sir Clements Markham from the committee of the school, adding that the University owes much to Sir Clements Markham for his efforts to promote the teaching of geography in Oxford during a quarter of a century. The generous gift from Sir Abe Bailey of 250*l*. a year for five years has enabled the committee to provide increased accommodation in Sir Henry Acland's house in Broad Street, thus relieving pressure on the Old Ashmolean building. More rooms are in preparation, and should be ready by Easter; meanwhile, in addition to the quarters specially assigned to the staff and students, a general reading-room has been opened, where any member of the University may consult books or maps. The committee again points out the need for an endowment for the teaching of geography in the University. Towards this, Lord Brassey and Mr. Douglas Freshfield have each offered to contribute 500*l*., provided an adequate additional sum can be obtained from other donors. Courses of lectures have been given by Prof. Herbertson, Dr. Grundy, Mr. Allorge, Mr. Beckit, and Miss MacMunn. Mr. O. G. S. Crawford, Keble College, has been appointed junior demonstrator and librarian. The geographical scholarship for 1910–11 was awarded to Mr. B. W. Baker, University College.

Prof. E. B. Tylor, F.R.S., has deposited on loan with the committee for anthropology a substantial portion of his library, to be used for the purposes of anthropological study within the University. The library will be housed, for the present, at Acland House, Broad Street.

Sheffield.—The council, at its last meeting, made the following appointments:—Dr. Sinclair White, to the professorship of surgery in the University, in succession to Mr. R. J. Pye-Smith, resigned; Mr. George Stanfield, to the post of demonstrator in engineering; and Mr. Ll. Lloyd, to the post of assistant curator of the zoological museum.

Mr. W. Buchanan, senior lecturer to Faraday House Electrical College, London, has been appointed professor of electrotechnics at the School of Mines (Transvaal University), Johannesburg.

A friend of Sir William Ramsay's, who desires to remain anonymous, has promised 2500*l*. towards the fund of 50,000*l*. required for the building of the new chemical laboratories at University College. The same donor will give a further sum of 2500*l*. provided the sum of 50,000*l*. is raised before Easter. The fund now stands at 31,277*l*.

A vacation course for the study of the structure, development, and ecology of marine algæ (Plankton and Benthos) will be conducted by Dr. O. V. Darbishire at the Dove Marine Laboratory, Cullercoats, Northumberland, during the Easter vacation. Instructions will also be given in the various methods of collecting, mounting, fixing, and cultivating marine algæ. Further information may be obtained from Dr. Darbishire, Armstrong College, Newcastle-on-Tyne.

We learn from *Science* that the U.S. General Education Board has made conditional grants as follows:—Brown University, 20,000*l*.; Carleton College, 20,000*l*.; Colorado College, 10,000*l*.; Dakota Wesleyan University, 10,000*l*.; Denison University, 15,000*l*.; Fisk University, 12,000*l*.; Mount Holyoke College, 20,000*l*.; Randolph-Macon College, 10,000*l*.; Swarthmore College, 15,000*l*.; and Wesleyan College for Women, 10,000*l*. From the same source we gather that the Bill increasing the annual appropriation from the State of Vermont to Middlebury College by 1520*l*. has been signed by the Governor. This will make the State appropriation to Middlebury 3200*l*. a year, beginning on July 1. The increase is "to provide additional instruction in the departments of pedagogy, in forestry, and in scientific branches related to the industries of Vermont." It is also stated that a gift of 10,000*l*. to Cornell University by Mrs. Florence O. R. Lang, of Montclair, N.J., will be used in the construction of a new building to house the shops of the Sibley College of Mechanical Engineering.

The University of Christiania will, in the beginning of September next, celebrate its centenary, having been founded by King Frederic IV. in 1811. Prof. K. Birkeland has kindly given us the following information relating to this celebration. Instructions have recently been sent to 226 universities or similar institutions of higher education, and to 113 learned societies, each being invited to send one delegate. It may be mentioned that the programme for the official festivities, as at present proposed, includes a reception banquet for the foreign delegates on September 4, while the actual centenary festivities will take place on Tuesday, September 5, and Wednesday, September 6. On the Tuesday, Björnstjerne Björnson's Cantate, "Lyset," will be rendered. This will be followed by the address of welcome to the foreign representatives of universities and academies, replies from groups of these representatives, and the presentation of addresses. On the Wednesday, honorary degrees and promotions will be conferred. A medal, struck in commemoration of the centenary, and various publications, will be distributed. The president of the festival committee is Prof. Brögger, rector of the University. The students have also appointed a committee, which is issuing thirty invitations for student delegates from other universities.

Mr. Jesse Collings has introduced into the House of Commons a Bill, which is influentially backed, to afford further facilities for the creation of Small Holdings. Side by side with the granting of further facilities to those who are desirous of becoming smallholders is a movement,

ıitiated by Mr. Collings, for promoting agricultural lucation and nature-study in public elementary schools. ocal education authorities may provide and maintain ıeans and facilities for the purpose of giving instruction ı any of the following subjects:—nature-study; fruit, ɔwer, and vegetable growing; poultry- and bee-keeping; ıdding, pruning, and grafting; cow- and pig-keeping; ilking; rotation of garden crops; nature and properties soils; use of manures; knowledge and choice of seeds; ructure, life, and food of plants; action of birds and sects on crops; choice and use of simple tools; packing uit, vegetables, and other produce for market. The ıportance of these legislative proposals, from a small-ɔlder's point of view, lies in the fact that they are signed to interest the children in rural districts in the cupations which ought, naturally, to constitute their ter-life. The Festival of Empire is devoting ten acres ıd some thousands of pounds to demonstrating along actical lines how the successful cultivation of small ɔldings may reclaim agricultural and rural districts. The ms and objects of the Small Holdings and Country Life ction of the Festival have the approval of the Board Agriculture and Fisheries, and experts are assisting in conduct and management under the auspices of various ricultural and cooperative organisations.

THE very representative Conference on Industrial Train-g, held at the Guildhall on Tuesday, February 28, was ɔened by a sympathetic message from his Majesty the ing. The following resolution was passed by an over-ıelming majority:—"That the national system of indus-ial, professional, and commercial training should be tablished, to which the children shall pass as a matter course (unless the parents are prepared to undertake eir future training), and without interval for a definite riod, to be thoroughly trained for entry into the par-ular calling for which they are best fitted, such training be under fully qualified instructors." The passing of is resolution marks an important change in public inion, and indicates a strong feeling that the school age ould be extended to about sixteen years of age, and that e education given during, say, the last three years of hool life should, whilst not neglecting the general educa-ɔn, be a preparation for the particular occupation the ild intends to follow. In the past it has been the prac-e to regard education as suitable only for those who tend to follow clerical occupations. The work of trade hools and of technical institutes has, however, shown at much may be done in schools and institutes under illed instructors to prepare for, and supplement, the ficient training of the workshop; but hitherto this has en done mainly in the evenings. It is now recognised at much better results would be obtained if the pupils ceived some sound practical training in the daytime at e end of their ordinary elementary-school career. deed, the changed methods of production due to the troduction of machinery, and to the consequent sub-vision of labour and decay of apprenticeship, has made me change in our system of training a necessity.

THE second volume of "Statistics of Public Education England and Wales" has now been published (Cd. 06). It deals with the financial statistics of the years 08, 1909, and 1910. The net total expenditure of the ɔard out of the Parliamentary Vote, after deducting propriations in aid, was, for 1909–10, 13,638,424*l.*, as ımpared with 13,485,233*l.* in 1908–9 and 13,272,624*l.* in 07–8. The grants to meet expenditure in respect of ementary education amounted to 11,095,420*l.*, as against ,039,281*l.* in 1908–9 and 11,023,121*l.* in 1907–8. Grants secondary schools amounted to 610,435*l.*, as against 6,107*l.* in 1908–9 and 342,393*l.* in 1907–8; for pupils in eparatory classes, pupil teachers, and bursars, 143,413*l.* in 09–10. Technical institutions, day technical classes, ıools of art, art classes, and evening and similar schools d classes absorbed 512,475*l.*, as against 493,927*l.* in the evious year; maintenance grants for training colleges, 0,985*l.*; and building grants for training colleges and stels, 60,102*l.* The Imperial College of Science and chnology in 1909–10 received 20,000*l.*, the Geological ıseum and Geological Survey 20,893*l.*, and the Com-ttee on Solar Physics 2119*l.* The only change of any importance in the present volume consists in the inclusion of tables giving particulars as to the salaries of supple-mentary, student, and pupil teachers on the staff of ordinary elementary schools. In previous years the salaries of certificated and "uncertificated" teachers alone were dealt with. It appears that in 1908–9 the average salaries of certificated teachers in Wales were: men head teachers, 146*l.* 9*s.*, men assistant teachers, 113*l.* 19*s.* 11*d.*, the corresponding amounts in the case of women being 109*l.* 16*s.* 9*d.* and 82*l.* 8*s.* 4*d.* In England the average salaries were higher for certificated teachers. Men head teachers earned, on the average, 173*l.* 11*s.* 2*d.*, and men assistants 124*l.* 7*s.* 3*d.* The amounts for women certificated teachers were 120*l.* 17*s.* 7*d.* and 90*l.* 3*s.* 8*d.*

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, February 23.—Sir Archibald Geikie, K.C.B., president, in the chair.—Miss M. **Robertson**: Trans-mission of flagellates living in the blood of certain fresh-water fishes. The goldfish in a pond at Elstree have for some years shown an infection of trypanosomes in their blood. Quite recently, trypanoplasma has also appeared. Upon investigation is was found that the leech *Hemiclepsis marginata* occurred in the pond, and effected the trans-mission of the parasites. A large number of these leeches were obtained from the Grand Junction Canal reservoir, which is only a short distance from the pond. The young of these were hatched out in captivity, and it was ascer-tained that the flagellates are not passed from parent to offspring. The parent leeches were invariably infected with trypanosomes derived from the fish in the reservoir, which frequently showed these parasites in their blood. The trypanosomes of perch, bream, and goldfish were found to complete their cycles in Hemiclepsis, and could be transmitted to clean goldfish by means of leeches. The specimens used in these experiments were always young laboratory-hatched Hemiclepsis. The trypanosomes of pike and rudd also complete their cycle in this leech, but the opportunity of passing these two forms into goldfish did not present itself. The cycles of the trypanosomes derived from these different sources are apparently identical. The main features are as follows:—The trypanosomes taken into the crop of the leech along with the blood multiply very rapidly, undergoing a marked change of form. After some days, slender forms begin to arise. These increase in number, and at the end of digestion, some time after the blood has quite disappeared, they come forward and lie in the proboscis-sheath in very large numbers. The form found in the sheath is a very slender, long creature of quite definite type; division has never been observed in this phase. When the leech feeds once more, these individuals are inoculated into the fish. The proboscis-sheath is always cleared of trypanosomes by one feed. After a clean feed the slender, inoculative type of trypanosome disappears from the crop of an infected leech, and the infection is carried on by short, broad forms. Conjugation has never been observed. If water is added to the blood of fish containing trypanosomes, the flagellates divide after a number of hours, probably in response to lowering of osmotic pressure in the fluid in which they find themselves.—Dr. B. B. **Boltwood**: Report on the separation of ionium and actinium from certain residues, and the production of helium by ionium. At the end of 1907 the Royal Society lent to Prof. Rutherford certain actinium residues, which were part of the material remain-ing after the separation of the radium by Messrs. Armet de Lisle, of Paris, from uranium residues acquired by the Royal Society. These residues, in weight 20 kilograms, contained a large quantity of lead, and were a very hetero-geneous mixture of elements. A preliminary examination made by Prof. Rutherford showed that actinium was present, and also a small quantity of radium. The amount of ionium, however, was much less than the theoretical amount to be expected if all of it had been removed with the actinium. The preliminary work of concentration was done by Messrs. Tyrer and Co., under the direction of Prof. Rutherford and Mr. Greenwood. This material was given to the writer for further concentration, and the paper

contains an account of the methods employed in the separation of the actinium and ionium. The ionium was finally obtained mixed with 1·8 grams of thorium oxide. The activity of this oxide, due to the ionium it contained, was about 3000 times that of an equal weight of uranium oxide. By counting the α particles from a thin film by the scintillation method, the amount of ionium present with the thorium was found to be equal to the amount in equilibrium with 5·3 milligrams of radium in a radioactive material. The actinium was finally concentrated to about 10 grams of material, which gave a final activity about 20,000 times that of uranium oxide. It was estimated that the amount of actinium separated was equivalent to the amount in equilibrium with 30 milligrams of radium in a mineral. Special experiments were made to test whether ionium was transformed into helium. The presence of helium was determined by its spectrum, and the volume produced was measured. The investigation showed that helium is produced by ionium as well as by all other products which emit α rays.—J. A. **Gray**: The secondary rays produced by β rays. Secondary γ rays are produced in different materials by the β rays of Ra*E*, the greater in amount, the greater the atomic weight of the radiator. The γ radiation observed from a preparation of Ra*E* can be greatly increased by a suitable disposition of the active matter and apparatus.—W. R. **Bousfield** and W. Eric **Bousfield**: The specific heat of water. The object of this investigation was to obtain a basis curve for the specific heat of water, for comparison with specific-heat curves of aqueous solutions. Former observers, using different methods, have obtained widely varying curves; thus for the specific heat of water at 80°, in terms of the 15° calorie, the following figures have been given, showing differences of 1 per cent.:—Barnes, 1·0014; Regnault, 1·0081; Lüdin, 1·0113. For the values in joules of the 15° calorie the following have been found:—Joule, 4·174; Griffiths, 4·198; Barnes, 4·184. The first part of the present investigation is concerned with the determination of the mechanical equivalent of heat in terms of the mean calorie from 13° to 55°, by a method of continuous-flow calorimetry. Mercury thermometers were used which could be read to 0·005°. An interval of 40° was taken, so that an error of 0·01° would not vitiate the result by more than 1 in 4000. Through a Dewar vessel containing about 3 litres of water, in which was an electric heater, there was passed a current of water, entering at about 13° and passing out at about 55°. The vessel was immersed in a bath kept at same temperature as contents of vessel. The top of the vessel was closed by a platinum box kept 10° higher. The electric heater, and the resistance used in series with it for determining the current by help of a battery of standard cells, were of novel type. Each consisted of a spiral glass tube of small bore, into the ends of which are sealed platinum electrodes. The tube is connected with a thermometer tube, so that the spiral forms a thermometer bulb. By calibrating the resistance against the reading of this thermometer tube, the resistance is accurately known, even when a current is passing. This type of resistance enabled the authors to surmount a difficulty apparently never considered by previous investigators. They have found that when a heavy current passes through an ordinary standard resistance, the resistance of the standard depends, not only on temperature, but also upon strength of current. This effect may be conveniently called the "thermoid" effect. The authors believe a liquid mercury resistance is free from any such effect. The continuous-flow experiments gave for distilled water $J_{13}^{55}=4{\cdot}182$. To get the curve for J from 0° to 80°, a weighed quantity of water was heated from 0° to 80° by stages which gave J_0^{13} J_{13}^{27} J_{27}^{25} J_{55}^{80}, the mean specific heats over the intervals. For this purpose, the capacity of the calorimeter was obtained from the value of J_{13}^{55} previously determined, and a separate research on the specific heat of glass was carried out in order to obtain the variation of capacity with temperature. From these an equation for the value J_0^{θ} was obtained, and then the value of J from point to point, from the equation

$$J=\frac{d}{a\theta}(\theta]_0^{\theta}),$$

The authors thus obtain

$$J=4{\cdot}2085-0{\cdot}003022\theta+0{\cdot}00007833\theta^2-0{\cdot}000000490\theta,$$

which gives for the value of the 15° calorie 4·179. [T]he resulting curve corresponds closely with that obtained [by] Lüdin by the method of mixtures, and differs considera[bly] from that obtained by Barnes by continuous flow w[ith] platinum thermometry.—Prof. C. **Niven**: The measu[re]ment of specific inductive capacity. The paper conta[ins] an account of work undertaken to determine the spe[cific] inductive capacity of liquids by the method of resonan[ce]. The frequencies of the discharge of condensers with [air] and with liquid as dielectric were compared by the cym[o]meter and dielectric constants of the liquids deduc[ed]. With some liquids, notably with water, the question [is] complicated by the conductivity of the liquid. The co[n]ditions of discharge through a conducting liquid are the[re]fore first determined, and the condition of resona[nce] between the two resonating systems found. This is sho[wn] to be of a simple character, reducing practically to wh[at] it would be if the conduction through the liquid w[ere] neglected. In some cases, water, for example, it [is] impossible to set up oscillations directly, but by int[er]posing in the circuit of the condenser another of consid[er]able capacity, the oscillations may be obtained. When t[he] capacity of this interposed condenser is relatively ve[ry] large, it has no appreciable effect on the frequency of t[he] oscillations produced, which are thus those of the liqu[id] condenser alone. Owing to the rapid variation of t[he] specific inductive capacity with temperature, spec[ial] arrangements had to be made to keep the liquid at [a] constant temperature while measurements were bei[ng] made. The results of a number of determinations [at] different temperatures are given for water and alcohol.

Zoological Society, February 7.—Prof. E. A. Minch[in], vice-president, in the chair.—Dr. W. N. F. **Woodlan[d]**: Structure and function of the gas-producing mechanis[m] ("red body") found in connection with the gas-bladd[er] of many teleostei (Physoclisti and Physostomi). Af[ter] summarising some of the principal facts known concer[n]ing these subjects, the author discussed various theori[es] already advanced to account for the details of gas-produ[c]tion, and showed that the most satisfactory hypothesis w[as] a combination of the views of Jaeger and of Nusbau[m] and Reis, supplemented by additional facts and sugg[es]tions then advanced in the paper.—Prof. J. C. **Ewar[t]**: Skulls of oxen from the Roman station at Newstead, M[el]rose. The author stated that examination of the sku[lls] from Newstead lent support neither to the descent of [the] European cattle from the Urus (*Bos primigenius*) nor [to] the descent of all European, Indian, and African bre[eds] from the Asiatic Urus (*B. nomadicus*). He dealt wi[th] the evidence to be derived from the maxillæ, the occipu[t] and the temporal fossæ, and stated his conclusions [as] follows:—(1) That the Celtic shorthorn (*B. longifrons*) [is] probably more intimately related to the zebu of Ind[ia] (*B. indicus*) than to the European Urus (*B. primigeniu[s]*). (2) That long premaxillæ are usually correlated with [an] occiput of the *B. primigenius* type, while short p[re]maxillæ are usually correlated with an occiput of t[he] *B. acutifrons* type. (3) That polled black Galloway cat[tle] and polled white "wild" Cadzow cattle are intimat[ely] related to the Urus, that flat-polled Aberdeen-Angus cat[tle] probably include amongst their ancestors an ancie[nt] Oriental race now represented by, amongst others, [a] Syrian breed with rudimentary horns, and that roun[d]-polled cattle may belong to a still more ancient Orient[al] race descended from *B. acutifrons* of the Punjab Siwalik[s]. —G. P. **Farran**: Copepoda of the family Corycæi[dæ] collected by Sir John Murray and Dr. C. W. Andrews [at] Christmas Island. The collection, though small in bu[lk], was exceedingly rich in species, and the genus Corycæ[us] was especially well represented. A new genus was pr[o]posed, and several new species were described and figure[d]. —H. R. **Hogg**: Some New Zealand spiders. The pap[er] was based on a small collection sent by Prof. Charl[es] Chilton, of Christchurch, New Zealand. Twelve speci[es] and eleven genera were represented in the collection, a[nd] a new local variety of *Tetragnatha ferox* and four ne[w] species were described.—Oldfield **Thomas**: Mamma[ls] collected in the provinces of Kan-su and Sze-chwa[n]

western China, by Mr. Malcolm Anderson, for the Duke of Bedford's exploration of eastern Asia. This collection, from a region hitherto almost unrepresented in the British Museum, was perhaps the finest that had ever come from China, at least so far as small mammals were concerned. Forty-seven species were included, represented by 350 specimens, presented, as on previous occasions, to the National Museum by his Grace.

Royal Microscopical Society, February 15.—Mr. Plimmer, president, in the chair.—E. **Heron-Allen** and A. **Earland**: New or rare species of Foraminifera found in the shore-sands of Selsey Bill, Sussex. The authors directed attention to the identity of the fossil Foraminifera of the Bracklesham beds with the living species found in Australian shore-sands. Recent specimens of *Bolivina durrandii* (Millett) and *Pulvinulina vermiculatis* (Brady) were shown, the only other known records being as regards the former from the Malay Archipelago and as regards the latter from tropical and subtropical seas. In addition to these, *Miliolina suborbicularis* and *M. rotunda*, *Dextuluria inconspicua*, var. *jugosa*, *Bolivina torterosa*, *Uvigerina asperula*, and *Sagrina dimorpha* were recorded as new to Britain. Schlumberayer's unique genus and species, *Hinderina brugesii*, was recorded from the Eocene clays, also the first fossil records of *Bulimina subtues* and *Discorbina polystomilloides*. The new species recorded were *Pulvinulina haliotidea* (H.-A. and E.) and *Nomionina quadriloculata* (H.-A. and E.). Microscopical specimens of these were also exhibited.—Lees **Curties**: A new dark-ground illuminator. This was made to the instructions of Mr. Nelson; it was so constructed as to work with slips ranging from 0·8 to 1·2 mm. in thickness, and gave a perfectly dark field with a Zeiss apochromatic 4 mm. lens of 0·95 N.A. The illuminator was provided with a fixed central stop, and also with a slot for utilising the apparatus as an oblique illuminator. A small dot placed on the front lens served for the purpose of centring the condenser to the optical axis.

Linnean Society, February 16.—Mr. H. W. Monckton, treasurer and vice-president, in the chair.—Mrs. L. J. **Wilsmore**: Some Hexactiniæ from New South Wales.—Rev. Canon **Norman**: Three species of harpactid copepoda.—The following papers were communicated by Prof. J. Stanley Gardiner:—Mr. **Hirst**: Report on the Araneæ, Opiliones, and Pseudoscorpiones.—G. A. **Boulenger**: List of the batrachians and reptiles obtained by Prof. Stanley Gardiner on his second expedition to the Seychelles and Aldabra.—Miss Mary J. **Rathbun**: The marine Brachyura from the Indian Ocean collected in 1905. It dealt with a large collection comprising 245 species and subspecies, 34 species and 3 subspecies being regarded as new to science, with 3 new genera. The results showed no connection with the West African crab-fauna.

Institution of Mining and Metallurgy, February 22.—Mr. Edgar Taylor, president, in the chair.—A. Beeby **Thompson**: The relationship of structure and petrology to the occurrence of petroleum. After describing the general structure of the important oilfields of the world, the author deals briefly with some of the local features which tend to modify the distribution of petroleum, as, for instance, the existence of faults in the strata, abrupt changes from oil-saturated sands to hard rock that is impervious to liquids, the lenticular distribution of oil sands, and the presence of water. Among the influences which have a bearing upon the distribution of oil in an operated field is the tendency of oil to follow certain channels, which probably represent lines of weakness that existed in the early ages of development, when high gas pressures were experienced. On this account, it is sometimes found that wells drilled at a later period in proximity to wells of large production will yield a comparatively small amount. In any case, the active development of a rich oilfield in which large volumes of gas are released must almost necessarily produce in course of time some changes in the distribution of the underlying petroleum. The author is at pains to show that with the development of oil sources are encountered some of the most wonderful and fascinating natural phenomena, and that no branch of mining is attended with greater interest or makes greater demands on the resources and ingenuity of the engineer in charge.—A. L. **Shrager**: Shaft sinking against water in fissured ground by cement injection. This paper comprises a brief description of a method of sinking shafts in water-bearing ground, the general result of which is practically to form a cofferdam of cement around the proposed site of the shaft. The particular shaft described in the paper was one sunk in a coalfield in the Pas de Calais basin, and full details are given, not only of the work carried out, but also of the cost, labour, and quantities of material involved.

CAMBRIDGE.

Philosophical Society, February 6.—Prof. Hobson in the chair.—J. J. **Lister**: The distribution of the Megapodidæ in the Pacific. The genus Megapodius consists, according to M. Oustalet, of some nineteen species. The distribution of fifteen of these extends almost continuously from Borneo to the New Hebrides and from the Philippine Islands to Australia. It thus covers an area in which the land masses are nowhere very remote from one another. There are, however, four outlying species far removed from the rest of the genus, namely, in Niuafou in the Tonga Group, the Pelew Islands, the Marianne Islands, and the Nicobar Islands. As the birds are incapable of long flight, the question arises, How is the distribution of the outlying species to be accounted for? It has been suggested that it may indicate the existence of a former land area by which all these remote islands were at one time connected. The object of this paper is to show that there is a good deal of evidence, negative and positive, to support the view that these outlying species may have reached their present habitats by the agency of the natives, by whom the eggs are highly valued as food. Niuafou is an active volcano 3½ miles in its longest diameter. The other birds inhabiting it are of species common to the Tonga Islands, though four, found in the other islands, are apparently absent from it. The birds are "protected" by the chief, and they exhibit a partial albinism, though in very varying degrees. The native name for the bird is *Mallow*, identical with that of the Solomon Island species and with that generally used by Malay hunters throughout the East Indies. The nearest species of the genus (in distance, but not in affinities) is that of the New Hebrides, some 900 miles to the west, no megapode being known from the intervening Fiji Islands, which consist of much larger and more ancient land masses. With regard to the Pelew Islands, Semper gives evidence showing that they consist of raised coral rock investing a volcanic basis formed by a submarine eruption in late Tertiary time. Quoy and Gaimard, the naturalists of the *Uranie*, visited the Marianne Islands in 1818–20, and state that the species there found was domesticated by the natives. M. Oustalet considers that there are undoubted affinities between this species and that from the Pelew Islands, and it is evident from the published figures that there is a close resemblance between the latter and the Niuafou bird. Wallace has expressed the opinion that the Nicobar bird has probably been introduced by the Malays. There is evidence that the species found in the Solomon Islands exists in some places in a domesticated or semi-domesticated condition. As the natives of the Pacific Islands were in the possession of fowls, dogs, and pigs when they were first visited by Europeans, the supposition that in some of their wanderings they may have carried megapodes with them, and thus established the outlying species in their present habitats, appears not improbable.—J. **Romanes**: Note on *Strongylocentrotus lividus* as a rock-borer. The specimen exhibited, which was collected on the west coast of Ireland, shows three echinoids occupying holes which they have excavated out of the solid rock. In cases previously described, the material which was removed appears always to have been much weathered. In this instance, however, the rock, which is a slate, is quite fresh, and as it is quite free from calcareous matter, the action must have been of a mechanical rather than a chemical nature.—A. J. **Grove**: Exhibition of sketches of a peculiar tracheal system of a mycetophilous larva (Diptera).

MANCHESTER.

Literary and Philosophical Society, February 7.—Mr. Francis Jones, president, in the chair.—Prof. W. Boyd **Dawkins**: The origin of the Roman numerals I.–X. It was suggested that these numerals were derived from a system of numeration employed by the inhabitants of Crete

during the Minoan civilisation. This conclusion was based on a comparison of the Roman numerals with a set of Minoan numerical symbols.—Prof. A. H. **Gibson**: The manner of motion of water flowing in a curved path. The conclusions which would appear to be justified as a result of the experiments described are:—(1) that whenever flow takes place past a curved solid surface, whether this is exposed to water on its concave or its convex side, the motion, except for the slowest velocities, is unstable; and (2) that in the fluid itself curvature with the velocity greatest on the *inside* of the path tends to stability, while curvature with the velocity greatest at the *outside* of the path tends to instability. Another fact which the experiments appear to indicate is that the tendency to eddy formation in the relative motion of a fluid and solid surface is greater, for a given relative motion, when the fluid, as a whole, is moving past a stationary surface than when the surface is moving through still fluids. This receives indirect confirmation from experiments by Stanton, Beaufoy, Froude, Dubuat, and Morin on the resistance of plane surfaces when moving through still water, or when held stationary in a moving stream.—Miss Margaret C. **March**: Studies in the morphogenesis of certain Pelecypoda. II.—The ancestry of the Gibbosæ. The ornament of the Trigoniæ, as shown by the ontogeny and phylogeny of modern species, develops from concentric to radial, with tuberculations developed on alternating radii. Fossil forms show the development of a third type of ornament, viz. diagonal by the junction of these alternating tubercles. Working from this basis, the Gibbosæ (part of the Glabræ, Lycett) can be traced back through the Undulata (Lycett) to the Triassic purely concentrically ornamented form *Myophoria curvirostris*.

DIARY OF SOCIETIES.

THURSDAY, MARCH 2.

ROYAL SOCIETY, at 4.30.—Reversal of the Reflex Effect of an Afferent Nerve by altering the Character of the Electrical Stimulus applied: Prof. C. S. Sherrington F.R.S., and Miss S. C. Sowton.—Carbon Dioxide Output during Decerebrate Rigidity (Preliminary Communication): Dr. H. E. Roaf.—The Alcoholic Ferment of Yeast Juice. Part VI. The Influence of Arsenates and Arsenites on the Fermentation of the Sugars by Yeast Juice: Dr. A. Harden, F.R.S., and W. J. Young.—Experiments to ascertain if certain Tabanidæ act as the Carriers of *Trypanosoma pecorum*: Col. Sir D. Bruce, F.R.S., and others.—Experimental Studies in Indian Cottons: H. M. Leake.

LINNEAN SOCIETY, at 8.—Dermaptera (Earwigs) preserved in Amber, from Prussia: Dr. Malcolm Burr.—Report on the Marine Polyzoa of the Collection made by Mr. J. Stanley Gardiner in the Indian Ocean in H.M.S. *Sealark*: Miss Laura Roscoe Thornely.—On the Mysidacea and Euphausiacea collected in the Indian Ocean during 1905: W. M. Tattersall.

RÖNTGEN SOCIETY, at 8.15.—Some Experiments with a 10,000 volt. Storage Battery: A. A. Campbell Swinton.

FRIDAY, MARCH 3.

ROYAL INSTITUTION, at 9.—Scents of Butterflies: Dr. F. A. Dixey, F.R.S.

INSTITUTION OF CIVIL ENGINEERS, at 8.—Lagos Harbour Survey, 1909–1910: H. Ellis Hill.

SATURDAY, MARCH 4.

ROYAL INSTITUTION, at 3.—Radiant Energy and Matter: Sir J. J. Thomson, F.R.S.

ESSEX FIELD CLUB, at 6 (at the Essex Museum of Natural History).—Further Notes on Moorlog, a Peaty Deposit from the Dogger Bank: H. Whitehead and H. H. Goodchild, with Notes on the Plants by Clement Reid, F.R.S.—Note on some Ichneumonstung Larvæ: Rev. W. K. Wyley.—Notes on *Plusia moneta* in Britain: C. Nicholson.

MONDAY, MARCH 6.

SOCIETY OF ENGINEERS, at 7.30.—Petrol Air-gas: E. Scott-Snell.

SATURDAY, MARCH 11.

ROYAL INSTITUTION, at 3.—Radiant Energy and Matter: Sir J. J. Thomson, F.R.S.

CONTENTS.

THURSDAY, MARCH 9, 1911.

WHAT CONSUMPTIVES OUGHT TO KNOW.

(1) *Advice to Consumptives, Home Treatment, After-Care and Prevention.* By Dr. Noel Dean Bardswell. Foreword by Dr. C. T. Williams. Pp. xv+144. (London: A. and C. Black, 1910.) Price 1s. 6d. net.

(2) *Consumption, its Prevention and Home Treatment. A Guide for the Use of Patients.* By Dr. H. Hyslop Thomson. Pp. 75. (London: Henry Frowde, and Hodder and Stoughton, 1910.) Price 2s. net.

(3) *Open Air at Home: Practical Experience of the Continuation of Sanatorium Treatment.* By Stanley H. Bates. With introduction by Sir James Crichton-Browne, F.R.S. Pp. 62. (Bristol: John Wright and Sons, Ltd.; London: Simpkin, Marshall, Hamilton, Kent and Co., Ltd., 1910.) Price 2s. 6d. net.

(4) *The Expectation of Life of the Consumptive after Sanatorium Treatment.* By Dr. Noel Dean Bardswell. Pp. v+130. (Edinburgh, Glasgow, and London: Henry Frowde, and Hodder and Stoughton, 1910.) Price 3s. 6d. net.

ONE of the most important features of the modern crusade against consumption is the attempt that has been made by those who are actively engaged in treating patients in sanatoria to make provision for the training of these patients in suitable methods of carrying on home treatment, after-care, and prevention. These skilled men see that it is impossible for most of the patients who have come under their charge to remain in the sanatorium for a sufficient length of time to ensure complete or permanent cure, and they desire to make the sanatorium a school in which the patient may be trained so to live and regulate his work that he may become and remain a useful and productive member of society. No one is better able to give such advice than is Dr. Bardswell, the medical superintendent of the King Edward VII. Sanatorium, and in the little unpretending book (1) now before us we have in few words and practical form just such advice as the consumptive requires.

Dr. Bardswell begins by pointing out the difficulties of laying down general rules for the treatment of individual patients, but shows that when principles are sound the details can gradually be fitted in; the general principles as laid down by Dr. Bardswell are the following:—

"1. Raising the general health of the consumptive to its highest possible pitch, thus restoring his power of resistance and arresting the disease.

"2. Maintaining it there long enough to justify the assumption that the disease is cured."

Dr. Bardswell indicates that although the first part of the process may be effected during a stay of some three to six months in a sanatorium, the second portion of the cure rests with the patient himself, the twelve months following the patient's discharge from the sanatorium being the really critical period of treatment.

Fresh air, without cold or discomfort is his first requirement; open windows, shelters and châlets, half-holidays and holidays in the open, and a change of air whenever possible. Health resorts and sea voyages, if judiciously indulged in, may be very useful, but they are by no means essential, and, indeed, where they involve fatigue may be actually harmful. The chapter on food is extremely practical and very condensed, and those interested in the subject may well peruse it carefully. Dr. Bardswell is of opinion that the consumptive is best without any alcohol at all, though he thinks that when convalescence has been thoroughly established there may be

"no harm in substituting a glass of beer or some light wine for the milk at meals. This is as far as I would go. Spirit in any form and at any time, but especially so between meals, should be absolutely avoided."

In the suggestive chapter on rest and exercise it is laid down that anyone suffering from pulmonary tuberculosis, or who has so suffered, should abstain entirely from any game or sport which entails sustained and severe physical exertion or sudden and violent muscular effort, whilst the ordinary indoor recreations, unless they can be adapted to the open air in fine weather, should certainly be demitted during treatment and convalescence. Smoking, especially before meals, should be avoided except in great moderation. Moreover, if there is any tendency to weakness of the throat smoking is absolutely negatived.

It will be seen that Dr. Bardswell is essentially practical in directing special attention to those points concerning which the consumptive so often requires advice and encouragement. Hints as to clothing, an account of the sanatorium treatment, the principles of which have to be carried out in the patient's own after-life until health is thoroughly established, occupation, emigration, infection, disinfection, are all carefully dealt with. The last couple of pages give in concise and admirable form advice which will be useful not only to consumptives but to those who, without becoming valetudinarians, wish to remain physically and mentally sound and vigorous. The man who lives by the thermometer and with the help of various nostrums will find in this book nothing to encourage him, but the man who believes in good, sound, common-sense and a healthy, active life will derive great encouragement from its perusal.

(2) The reproach sometimes cast at the medical specialist, that he is too theoretical and pays but little attention to the practical details and surroundings of his patient, can certainly not be laid at the door of Dr. Hyslop Thomson, who, in a small compendium, gives a series of very practical hints which may be read with very great advantage by those who are recovering from consumption. This little work is another sample of the book that removes all excuse for ignorance, even amongst the laity, of the more important facts and factors to be noted and observed concerning the cause, course, treatment, and result of tuberculosis. Lowered vitality, inherited susceptibility, exposure to infection, the nature of infection,

are all treated of, and the special and general conditions under which tuberculous infection may be carried, and the conditions of the patients who may most readily be infected by that infective material are all of them laid down. The precautions to be taken against infection, the necessity for home treatment, and for the carrying of it out in a rational and intelligent and persevering fashion are insisted upon strongly. The following quotation might well be written up in large letters wherever men congregate:—

"The education of all consumptives to this view, that in the warfare against tuberculosis, the arrest of the disease, and the prolongation of life depend upon the care with which home treatment is carried out by the patient would materially aid in diminishing the death rate from the disease."

It is, of course, obvious that any such patient, if he be wise, will report himself at intervals to his doctor for examination and advice.

The various rules laid down as to observation of temperature, rest, exercise, diet, and the like, simple and readily followed out, are exceedingly valuable. The concluding paragraph of the book is perhaps a good type of the advice here given:—

"Too frequently the consumptive spends on useless nostrums money which would be far better employed in purchasing good food and procuring fresh air. All the so-called cures which are advertised for consumption will avail little in checking and curing the disease, compared with an intelligent effort on the part of the patient to carry out the principles and practices of open-air home treatment."

(3) Mr. Stanley H. Bates, in this brochure, gives a very succinct and clear account of his own experience in post-sanatorium treatment of consumption. Mr. Bates defines his purpose as being

"to give, in as clear a manner as possible, practical advice in the home-treatment of consumption drawn from three years' actual experience. It is written for the benefit of those who find themselves placed as I was three years ago, when, after six months at a sanatorium, I was advised to continue the treatment at home; and is an attempt to pass on to them the knowledge I should have been glad of then, but had to learn by experience."

After outlining the advantages of an outdoor sleeping shelter, the author gives a series of most practical details as to site, construction, and ventilation, protection from rain, materials, cost, and general construction and furniture, of an outdoor shelter. It is interesting to note how the ideas of the author gradually developed, and how at very small cost he has been able to evolve an open-air shelter that has practically all the advantages of a sanatorium shelter. He is a good example of the man who fights the disease whole-heartedly, and he certainly has deserved his victory.

"Wage continuous war with it," he says, "allow it no respite, and your victory will be accomplished the sooner. Some amount of moral courage and perseverance will be required for the purpose of your recovery. Energetic measures, however, and a determination to get well without delay, will go far towards rendering it sure and speedy. It is far better to make your recovery complete before returning to your occupation, than to run the risk of having to leave it again for the purpose of a further course of treatment. If your illness has upset your plans, make others; if a change of occupation is necessary, resign yourself to the form of life it will be best for you to follow. You will find more than sufficient compensation in the exuberance of health which you will enjoy as the result of your open-air principles."

This is good philosophy and sound common-sense. Mr. Bates's book should be in the hands of everyone who wishes to obtain the best results possible in his or her own care.

(4) Dr. Bardswell, in a concise abstract of the cases that have come under his observation in King Edward VII. Sanatorium, directs attention to the fact that it is now possible to obtain some indication as to the expectation of life of the consumptive, especially when based on a careful classification of a series of patients, living under favourable conditions, examined before and after treatment. He shows that this double classification is of importance because at the one extreme the patient is observed under what may be looked upon as the most unfavourable conditions, whilst at the other the course of the disease and the condition of the patient may be assumed to be considered in their most favourable aspects. How complicated and varied are the symptoms in cases of tuberculosis may be gathered from the classifications given by Dr. Bardswell, but it is obvious that without the data on which the classifications are based it would be impossible to give any intelligent and trustworthy prognosis, the classification on discharge being as important as is that on admission in so far that it offers additional ground for prognosis.

Marked differences persist at the stage of treatment, at which the cases leave hospital. This is evident from the fact that they are divided into "apparently cured," "arrested," "improved," "unimproved," or "progressive." Examining these cases at later intervals—that is, after periods of from one to five years—Dr. Bardswell gives the results of the open-air treatment of 241 cases discharged between the years 1901 and 1905, taking as the time basis of his report the year 1909, and points out that of these patients there were 62 suffering from incipient phthisis, of whom 46 were still alive, 6 of these dating back to the year 1901, 12 to the year 1902, 14 to the year 1903, 11 to 1904, and 3 to 1905, so that all of them were alive and well for at least four years after they had been discharged, and some of them for nine years. In only one case was the disease active when the patient was discharged, and he is now dead. Of the other cases of incipient phthisis 10 of the 62 were dead and four could not be traced.

Such results are certainly very satisfactory. In cases where the diseases was moderately advanced on admission the results were far less satisfactory. Of 95 treated 47, or 49·4 per cent. against 74 per cent. in the first group were well in 1909, 10 were alive, but were still suffering from the disease, and 35 or 36·8 per cent., against 17·6 in the first group were dead, and three patients had been lost sight of entirely. In the group in which the disease was far

advanced on admission, 84 in number, only 6, or 7·1 per cent., had been cured, that is, were well, in 1909. Only four others were alive, while 74, or 88 per cent., were dead.

It should be noted that Dr. Bardswell deals rather with what may be called the "chances of survival" than with the "expectation of life" as defined by actuaries. In regard to the capacity for work—that is, ability to work or to live an ordinary life—of the patients now described as well, he gives some interesting figures. Here, again, the incipient cases afford by far the greatest percentage of workers. Of those working at the above mentioned dates, it was found that 59 per cent. were able to do full work, 10·2 per cent. could work short hours, 10·2 per cent. had given up work, and 20·4 per cent. had died. From amongst the moderately advanced cases, 32 per cent. were doing full work, 7·3 per cent. were working short hours, and 24·5 per cent. had given up work entirely; 36·6 per cent. were dead. Of the advanced cases only 4 per cent. were working short hours, and 94 per cent. had died. The prospect of any advanced case ever doing a normal amount of work is, therefore, very small indeed; but, as Dr. Bardswell puts it, the "outlook for the moderately advanced cases is very fair and for the incipient cases good."

It is interesting to note that in a commentary on these cases Dr. Bardswell states that there are few morbid conditions that are so rapidly and markedly benefited by appropriate treatment as is tuberculosis, but that this treatment must be prolonged there seems to be little doubt, prolonged considerably beyond what the patient, from his feeling of well-being, usually considers necessary. At the same time, he believes that the patient may remain too long under sanatorium treatment. Some patients lose their self-reliance and become nervous as to their condition, and develop into "sanatorium hypochondriacs." These are usually the patients who do not obey instructions or who do not respond to treatment. Such patients, he believes, should go home or be sent abroad, and be encouraged to "get out of themselves" and find other interests.

Dr. Bardswell is also a great believer in the importance, as factors in success, of the temperament and character of the patient. He says:—

"To the consumptive who possesses earnestness of purpose, common-sense, courage, and patience, cure is much more probable than in one who lacks these characteristics. It has been well said that a fool never gets well of consumption."

Whatever else may be said, it must be admitted that the sanatorium treatment has prolonged by a very considerable span the life of the consumptive patient. Dr. Williams's estimate of the average duration of life of selected cases of consumption in the pre-sanatorium days was eight years. Dr. Noel Bardswell's figures indicate an improvement on this, for he finds that of every one hundred cases of consumption, taking them as they come, and without any attempt at selection, fifty will die within a period of from four to nine years after admission to the sanatorium, but the remaining fifty will be found for the most part to be enjoying good health after the same period. A study of the abstracts of Dr. Bardswell's cases seems to bear out his contention. This work may be commended to the attention, not only of those who expect too much from the sanatorium treatment, but also to those who are prone to belittle it.

EGYPTIAN RELIGION.

The Book of the Dead. By H. M. Tirard. With an introduction by Prof. E. Naville. Pp. 170. (London: S.P.C.K., 1910.) Price 3*s.* 6*d.*

THIS little book will no doubt interest the many amateurs of Egyptology in this country, but it cannot be said to be of any scientific value. For this it is too conventionally "religious" in tone; a cult of "one supreme God" is supposed to have existed amid the chaotic polytheism of Egypt (there is no proof of any such conception before the time of Akhenaten), and the commonplace belief in the immortality of the soul, which is shared by all mankind, is credited to the Egyptians as a special virtue. Also the book is not historical and archæological enough in treatment. We hardly realise from Mrs. Tirard's pages that the Egyptian religion had a long history, and that it was not the same at all periods; nor, to take a concrete instance, are we told by her that the *ushabti* figures, so typical of the interments of the dead, were unknown until half Egyptian history had been accomplished, their place being taken in the earlier ages by those remarkable models of workmen and boatmen which are among the chief treasures of our museums. All the typical prayers from "The Book of the Dead," about the *ushabtis,* the fields of Aalu, and so forth, which we regard as so characteristic of Egyptian religion, were not characteristic of it for half its period of existence.

The interest of the Egyptian spells and charms relating to the souls of the dead, which we call "The Book of the Dead," is to the anthropologist very great, as he gains from it most interesting views of the original savage state of the African ancestors of the Egyptians. But a strictly scientific book on these spells is yet to seek. A critical survey of the material would separate the early magical incantation from the later prayers and hymns of the civilised age. The pious conservatism of the Egyptians preserved the childish gabble of the primitive age side by side with the later prayers. Both are habitually jumbled up together in books on the Ancient Egyptian religious writings, and to the primitive magical gibberish is ascribed a hidden and recondite meaning (on the principle *omne ignotum pro magnifico*) which it never possessed. It never was more than the "patter" of the savage medicine-man. He was the spiritual ancestor, no doubt, of the cultured priests who wrote the hymn to Amen quoted by Mrs. Tirard (p. 157); but this is very far removed above the average calibre of "The Book of the Dead," of which it is no part, and seekers after real religious feeling in Ancient Egypt will go to these hymns and psalms, which have nothing to do with the tomb, its ghosts, and magical paraphernalia, the "clotted absurdities" to which Mrs. Tirard has devoted such careful and painstaking labour, which, however, has, we fear, hardly

been critical enough to be of any value to the anthropologist.

Prof. Naville is quite justified in congratulating (on the introduction which he prefixes to the volume) Mrs. Tirard on the extent of her knowledge of the Egyptian religious writings. It is her uncritical treatment of her own knowledge that we regret. There are few actual mistakes in matters of fact in the book, the most serious perhaps being the statement that the word *makheru*, "justified," is never used of the living, only of the dead; this is incorrect, as instances of *makheru* being used of the living are known. In a matter of faith rather than of reason, we do not share her belief that the "Prince of Wales's Feathers" are derived from the Egyptian feather symbolical of "Truth," or rather, "Right." Where are the intermediate stages between the old Egyptian feather-emblem and the day when the Black Prince did *not* take the three ostrich plumes from the helmet of the slain King of Bohemia? For we know that at Poitiers the blind king's crest was an eagle's wing, and that the picturesque legend of the origin of the Prince of Wales's Feathers has no basis in fact.

In her citations, Mrs. Tirard usually follows the masterly translation of Prof. Naville.

ANATOMY OF SEDGES.

Anatomy of the British Carices. By F. C. Crawford. Pp. xiv+124+xx plates. (Edinburgh: Oliver and Boyd, printed for private circulation, 1910.) Price 7*s.* 6*d.* net.

FRANCIS CRAWFORD was an enthusiastic worker in pursuits that attracted him; a remarkable man in that, after success in business enabled him to retire at forty-five, he could crowd so much acquisition of natural history knowledge and collections into the remaining twelve years of his life. Botanist, ornithologist, geologist—an all too brief biographical sketch of the author precedes the introduction by Prof. Balfour, who, as his lifelong friend, gives in a few touches fuller insight into the lovable character of the man. His sudden death, soon after the MS. was in the printer's hands, in February, 1908, deprived the work of the author's revision; and Prof. Balfour, who edited it, deemed it best, in spite of its unconventional phraseology, to let the book go forth "as Frank Crawford wrote it."

Crawford had no laboratory training, and, taking to botanical work late in life, could not readily acquire the use of its technical terms, or always consent to their fitness. "If people can't understand plain terms," he used to say, when his vernacular expressions were criticised, "so much the worse for them." This accounts for the frequent blend of scientific and homely phrases. The section of a midrib (p. 49) is described as a "round knob with a blunt point"; the stem of *C. remota* (p. 37) is "roundish and difficult to define, very bumpy"; the section of a leaf of *C. hirta* is "long, narrow, twisting about"; and in another species the "vascular bundles . . . don't reach to the epidermis." But these quaintnesses would not puzzle any reader.

What is a more troublesome deviation from usage will be found in the abbreviations and technical terms that need explaining, being relegated to casual footnotes. What is the meaning of the sentence on p. 8, "The bundle of *vulpina* var. *nemorosa* is in the median plane, but the patch of sch. does not reach to the apex, there is therefore a point of par."? The reader looks in vain for a list of abbreviations; it is in footnotes on pp. 2, 7, that to the two used here and constantly further on he finds a clue. The terms "involute" and "revolute" bear the meaning of incurved and recurved (p. 4), while "lumen" is not explained at all.

Such minor flaws detract, however, but little from the real value of an admirable book, which has the great merit of being pioneer work, at least in regard to this genus. The field botanist will be grateful for the inside details of stem, leaf, and rhizome, of which for the most part he has been woefully ignorant. All these details are set forth in the clearest style, in type that leaves nothing to be desired.

By Prof. Balfour's advice, Crawford tells us in his introduction, he collected, with the help of the Rev. E. S. Marshall and some others, fresh material to work on in preference to dried herbarium specimens. He first photographed a flower portion, and put other portions in spirit for winter work. From these he took sections of the stem, leaf, rhizome, and root, and prepared photomicrographs of the best, magnifying about 40 diameters. Little or nothing was obtained from dissecting the flowers; these are therefore not touched on in the "Anatomy." Many sections of the other parts were selected to figure, and with drawings of highly magnified stomata, &c., occupy twenty plates. These are done with a clearness of definition and a fidelity of detail that reflect great credit on both photographer and engraver.

The description of the figures in the plates, p. 115, is concise and accurate enough, but the numbers of the plates might have been added for convenience of reference, and as the species in this list of figures are in no order, and several occur again and again, the index should have embraced these pages as well as the rest.

In the special anatomy, as Crawford terms his descriptive account of the species, which forms the body of the work, each part of the plant in section (below the inflorescence) is given in detached paragraphs. *C. chordorrhiza*, Ehrh., is a capital example, being fully illustrated as well as minutely described. Crawford discovered in this species remarkable divergences between its aërial and underground rhizomes. There is no doubt where this came from, as there is but one British locality. The same with *C. trinervis*, which he collected at Ormesby by the present writer's direction. But the locality is a *desideratum* in almost every case, and might be supplied from the labelled specimens or photographs, which have been deposited at the Royal Botanic Garden, Edinburgh.

Most interesting is the success attained in differentiating more thoroughly the triad so perplexing to novices, *C. laevigata*, Sm., *binervis* and *distans*; in confirming on the whole the suspected origin of several hybrids, and in testing the claims of some varieties. Among these last the evidence does not

support the alleged distinction between *C. vulpina* and its var. *nemorosa*, *C. canescens*, and its var. *robustior*, *C. diandra* and its var. *Ehrhartiana*; shows some difference between *C. Goodenowii* and var. *juncella*, much more between *C. binervis*, Sm., and var. *Sadleri*, Linton, which are farther apart than has been supposed.

This posthumous work, which throws more light on the *Carices* than most of us expected, owes its inception and completion to its distinguished editor, but it is a fine memorial of the persevering toil and ability of its lamented author, which must find its way into the hands of every botanist who pretends to a knowledge of the genus.

EDWARD F. LINTON.

TABLES OF SYMMETRIC FUNCTIONS.

The Symmetric Function Tables of the Fifteenthic, including an Historical Summary of Symmetric Functions as Relating to Symmetric Function Tables. By Prof. F. F. Decker. Pp. 16+tables. (Washington, D.C.: Carnegie Institution, 1910.)

THE publication of this paper is an example of the excellent work that is being done by the Carnegie Institution of Washington, over a wide field of science, under the fostering care of Dr. R. S. Woodward.

The formation of Symmetric Function Tables dates from the first decade of the nineteenth century, when Meyer Hirsch gave them up to and including the 10^{ic}. These tables give the expression of a symmetric function of the quantities, $\alpha_1, \alpha_2, \ldots \alpha_{10}$, in terms of the elementary symmetric functions thereof, $p_1, p_2 \ldots p_{10}$, where

$$(x-\alpha_1)(x-\alpha_2)\ldots(x-\alpha_{10})=x^{10}-p_1x^9+\ldots+p_{10}.$$

According to modern notation and nomenclature a function

$$\Sigma\alpha_1^{\pi_1}\alpha_2^{\pi_2}\ldots\alpha_{10}^{\pi_{10}} \text{ or } (\pi_1\pi_2\ldots\pi_{10})$$

is thus expressed in terms of quantities

$$p_s=\Sigma\alpha_1\alpha_2\ldots\alpha_s \text{ or } (1^s),$$

the exponents of the quantities, α under the sign of summation being merely assembled in a bracket.

Ex. gr. $$(2^2)=(1^2)^2-2(1)(1^3)+2(1^4),$$

and it will be observed that each term on the eight involves four units, and each is said to be a separation of (1^4). Mr. Decker's tables, like the earlier ones to which he refers, express all the functions $(\pi_1\pi_2\ldots)$, where $\Sigma\pi=15$ in terms of separations of (1^{15}), and a reader of his historical summary might suppose that nothing further had been done in the way of tables of symmetric functions. The facts are quite otherwise, for several remarkable extensions have been made to which Mr. Decker makes no reference whatever. So far back as 1888, in the *American Journal of Mathematics*, an analogous theory was shown to exist in regard to the separations of any partition whatever, and a complete set of tables, direct and inverse, up to weight six inclusive, was given in the *Journal*; a law of symmetry corresponding to the Cayley-Betti law and several other laws of symmetry were established. For example, one row for weight six and the separable partition (321) is:—

$$2(51)=(3)(21)+(2)(31)-(1)(32)-(321).$$

It was also shown that the weight might be zero or negative, and the separable partitions involve zero and negative parts without interference with the construction of the tables or with their fundamental properties.

Further, also in the Phil. Trans., R.S., 1890, the tables and properties were extended to the symmetric functions of several systems of quantities and specimen tables were given. It is necessary to say so much, as otherwise a reader might be grievously misled.

The historical summary in regard to a single system of quantities and the separations of (1^n) is well given by Mr. Decker. He is in error in ascribing formulas for calculating the constituents in each of the first four lines or columns to Roe; the first of these is nothing more than Waring's law, extended by the law of symmetry; the others are readily obtainable from it, and have long been in use by calculators.

The chief use of the formation of tables of these functions has been that the construction has led to the discovery of new theorems which have been of use in other departments of mathematics; in particular, remarkable differential operators were thus brought to light which have been successful in opening up problems of the magic square description, which had defied analysts from Euler to Cayley. Also the theory of non-unitary symmetric functions was shown to involve that of the covariants of binary quantics.

It is disappointing to find that Mr. Decker's laborious work with the 15^{ic} has not resulted in the discovery of theorems of wide application; this is not surprising, because it is fairly certain that previous workers have taken the principal plums out of this particular orchard; but, this being so, there does not appear to be any sufficient reason for continuing this series of tables.

Mr. Decker's table is beautifully produced, and he seems, while detecting errors or misprints in the lower tables, to have carried out a good system of checks to ensure freedom from error in his own.

P. A. M.

WORKSHOP MATHEMATICS.

Shop Problems in Mathematics. By W. E. Breckenridge, S. F. Mersereau, and C. F. Moore. Pp. vii+280. (Boston and London: Ginn and Co.) Price *4s. 6d.*

THE authors' aims in producing this book have been to impart to the student information in regard to the more important points in shop work, such as the names of the parts of machines used in wood and metal working, together with the materials employed, and also to give a thorough training in the mathematical operations that are useful in shop practice and science. In carrying out these ideas, about two-thirds of the space available are occupied in calculations applied to timber, house building, machines, pattern-making, and foundry work, forgings, screws, and screw-cutting, and the gas engine. The latter part of the book is taken up with a review of calculation with short methods.

The book is decidedly American in its arrangement,

treatment, and nomenclature, and is evidently designed for the use of students in manual training high schools. One of the objects, we are told, is to correlate the work of the mathematical classroom with that of the departments of mechanic arts and science. For example, a student is beginning to handle boards in the shop and at the same time is commencing the study of algebra; it is advised that he be assigned some problems on board measure, together with a review of work in fractions. It is, without doubt, advisable to have a general working arrangement between the mathematical classroom and the applied science departments, but the arrangement, in our opinion, may be, and often is, carried too far. There is a danger, if the connection be too intimate, of the student specialising on his own account by giving his earnest attention to those portions of the mathematical work which are adapted to fit the trade he intends following, and giving scant attention to the other portions. It is rarely the case that books of the nature before us succeed in becoming an integral part of an effective educational system, despite the fact that they may be, as this one is, clearly written, full of useful information, and well arranged.

There are a few slips; thus on p. 107 appears an exercise on the work done while punching a hole. It is impossible to work this problem without an autographic record of the operation, although no hint of this is given. Many teachers in trade schools in this country will be glad to inform themselves of American methods through the medium of this book, despite the fact that they may find difficulty in placing it in their pupils' hands owing to the nomenclature, to which reference has been made.

SPECTROSCOPY.

Handbuch der Spectroscopie. By Prof. H. Kayser. Fünfter Band. Pp. vi+853+Täfel ii. (Leipzig: S. Hirzel, 1910.) Price 48 marks.

As is well known, Prof. Kayser planned to finish his great handbook in four volumes, but owing to the mass of the material dealing with absorption the third volume was divided into two. The same trouble has arisen over the fourth volume on the original scheme, and the present volume contains only the spectra of the elements, arranged in alphabetical order, down to and including nitrogen. The sixth volume, which is to appear shortly, will contain the spectra of the remaining elements, and will conclude the physical spectroscopy.

As Prof. Kayser points out in his introduction, it would have been very satisfactory to include under each individual element a complete account of the work that has been carried out on its spectra under varying conditions of illumination. This would have entailed, however, the expansion of the book by several volumes, and therefore the details that are given have been limited. In the case of the fifty elements dealt with in the present volume, tables of the wave-lengths of the lines in the arc and spark spectra are given, and there also appears an account of the work that has been carried out upon these spectra of each element. Although this has of necessity to be brief, yet Prof. Kayser has dealt with the various investigations in a critical manner. In one or two cases is this especially to be remarked, and the article on the spectra of carbon stands out particularly as a fine critical review of the many contributions to the literature of the subject.

One great difficulty faces anyone who attempts to collate the various measurements of the spectra of substances, and that is the question of the standards upon which these measurements are based. As is well known, for the eight years between 1885 and 1893, the standard generally employed was that of Ångström's map as corrected by Thalén; this was superseded by Rowland's normal solar spectrum, which differed from the previous one in an irregular manner. Later it was shown by Prof. Kayser himself that the coincidence method used by Rowland with his concave gratings is not to be depended upon, and this was borne out by Fabry and Perot, who proved by their celebrated series of interference measurements that the Rowland scale is also irregular in its accuracy. As a result of the discussion held at the meeting of the International Union for Solar Research, a new standard has been set up by Fabry and Buisson, based upon the interferential comparison of a number of equidistant lines with the Michelson cadmium standard. This, however, is too recent to have had very much influence on comparative measurements. As a result of the fact that the three standards are not capable of accurate comparison, it is easy to see that very great accuracy cannot at present be claimed for many of the published spectroscopic measurements. Prof. Kayser remarks that the accuracy cannot be depended upon to within 0·1 tenth-metre.

Another difficulty that is met with in collating emission spectra is the relative intensity of the lines. It is manifest that it is next to impossible to standardise these intensities, for they vary so much with the method of excitation and also with the sensibility curve of the photographic plate. Different experimenters, moreover, have used different scales to which the intensities are referred. The values given therefore can only be taken as a general guide to the brightness of the lines, and cannot be considered of much value in comparing the spectra of different elements.

There is no doubt that this volume is a very worthy follower of the first four in the series, and must prove an indispensable addition to the library of everyone interested in emission spectra. Above all, it shows the directions in which work, and that most important work, still remains to be done.

E. C. C. B.

OUR BOOK SHELF.

Subconscious Phenomena. By Hugo Münsterberg, and others. Pp. 141. (London: Rebman, Ltd., n.d.) Price 5s. net.

For the purpose of arriving at some unanimity, if possible, on subjects regarding which there exists a certain amount of diversity of opinion it has recently become the fashion among psychologists to write a *symposium* in which each contributor gives expression to his views. The present work, produced under the editorship of Dr. Morton Prince, is of this nature and

from it we learn what Münsterberg, Ribot, Jastrow, Prince, Janet, and Bernard Hart mean by the subconscious. That such a work serves a useful purpose may be gathered from the fact that, as the master of the symposium states in his introduction, there are six recognised meanings of "the subconscious":—

(1) That portion of consciousness which for the moment is outside the field of attention.

(2) Split-off or dissociated ideas, such as automatic writing.

(3) A subliminal, secondary, subconscious "self" constituted and elaborated from such dissociated ideas.

(4) A combination of dissociated and forgotten ideas.

(5) The subliminal reservoir of consciousness from which ideas are drawn into phenomenal consciousness.

(6) Certain neural processes unaccompanied by any mentation whatsoever.

Most of the writers take the view that subconscious phenomena are physiological and not psychical processes, the underlying reason in all being that they are not memories, ideas or anything else of which mentation is composed.

Janet, of course, limits the subconscious to such abnormal states as are encountered in hysteria and psychasthenia, and Bernard Hart considers that the marginal elements of phenomenal consciousness (the *subconscious* of Stout), dissociated portions of phenomenal consciousness (the *co-conscious* of Morton Prince and the *subconscious* of Janet) and the non-phenomenal conceptual *unconscious* of Freud all form part of the material of psychology and not of physiology. It need scarcely be said that a symposium by such writers is above criticism; they criticise each other.

Mikroskopische Untersuchungen über die Übereinstimmung in der Struktur und dem Wachstume der Tiere und Pflanzen. By Dr. T. Schwann. Edited by F. Hunseler. Pp. 242+iv Taf. (Leipzig: W. Engelmann, 1910.) Price 3.60 marks.

AT a time when the accumulation of the facts of animal and plant structure threatened to prevent a clear conception of their true value, this famous memoir by a distinguished pupil of Johannes Müller converted histology into a rational branch of science. Schwann, who effected this profound change, based his method on development. He pointed out that "there is a common principle of development for all the elementary parts of the organism," and in so doing founded (with Schleiden) the cell-theory upon which modern physiology and pathology are based. The cellular nature of animals and plants had already been demonstrated, but there was no general hypothesis to "colligate" the facts. This Schwann supplied. He not only confirmed facts of cellular structure, but, in a refreshingly broad way, and moving with the ease of genius amongst a multiplicity of data that would have bewildered a lesser mind, he brought forward the evidence for the origin of the tissues and enunciated clearly his views on the nature of life.

To Schwann the organism is a beehive, as Huxley said in his famous essay on this very treatise. Its activities are the expression of the myriads of cell-changes, each independent of all the rest. To Schwann, and almost against his better judgment, the organism was, indeed, the product of its cells, and its cell the result of the crystallising of a "cytoblastema." Though in some ways we have outgrown this essay, its influence will probably always be felt, and when histology, as to-day, has become incapable of large views from the overburdening load of descriptive data, we realise the need of another Schwann; let us be thankful for the physiologist who by his developmental hypothesis put the subject-matter into a definite problem and offered a feasible answer.

Determinación de la Latitud por la Observación de Distancias Cenitales de la Estrella Polar. By C. Puente. Pp. 227. (Madrid: Observatorio Astronomics de Madrid, 1910.)

THIS is a monograph on the method of determining the latitude of a place from observations of the zenith distances of Polaris, at a known time. There is nothing new in this method, which proceeds on the ordinary lines of developing the latitude in a series of ascending powers of the polar distance, but the author has put the discussion out with great clearness and considered very carefully the terms that must be taken into account, according to the degree of approximation needed, as well as the most suitable formulæ for use when Polaris is near the upper or lower culmination. The methods of observing by means of theodolites, the instrumental adjustments, and the precautions necessary to be taken to ensure accuracy are detailed with very great care, the instructions being evidently intended for those who have had little practice. Numerous examples are worked out by different methods, and we have the ordinary curiosity of a latitude determined to the hundredth of a second when the microscopes read only to half seconds, and the time is observed no nearer than a second. Some of the results are so accordant that the ordinary observer must despair of attaining a similar accuracy. The greater portion of the book contains auxiliary tables for accelerating the reduction. Some of these have been extended from Albrecht's "Formeln und Hilfstafeln für geographische Ortsbestimmungen." and are available only within the limits of the Iberian Peninsula.—The more important of the tables include values of $\frac{2\sin^2\frac{1}{2}t}{\sin 1''}$, $\log\frac{2\sin^4\frac{1}{2}t}{\sin 1''}$, also $\frac{\cos\phi\cos\delta}{\sin(\delta\pm\phi)}$ where t, ϕ, and δ have the ordinary signification.

Calculus Made Easy. Being a very simplest Introduction to those beautiful Methods of Reckoning which are generally called by the terrifying names of the Differential Calculus and the Integral Calculus. By F.R.S. Pp. viii+178. (London: Macmillan and Co., Ltd., 1910.) Price 2*s.* net.

THE author of this little book writes as if it were the first of its kind, and in encouraging his readers he continually jeers at the professional mathematician in what might be regarded as reckless nursery language. In spite of such faults, we have no doubt that the book will be useful to schoolboys who need the ideas of the calculus in their study of physical science. The young engineer or the clever schoolboy will think it illogical and slipshod to leave $(dx)^2$ *out of consideration, as it is inconsiderable* in comparison with the other terms of $(x+dx)^2$, and he will say that there is only a pretence in the proof of the differentiation of x^n; he will probably look upon the introduction of the expansion of $(1+1/n)^n$ when n is indefinitely great, as not quite playing the nursery game.

Einführung in die Biologie. Ein Hilfsbuch für höhere Lehranstalten und für den Selbstunterricht. By Dr. W. Schoenichen. Pp. viii+215. (Leipzig: Quelle and Meyer, 1910.) Price 2.60 marks.

IT is difficult to understand to whom this little book is intended to appeal. It might almost be described as a scrap-book of illustrations, borrowed mostly from other text-books, and strung together with a minimum of letterpress. The subject-matter is treated from the point of view of physiology rather than that of comparative anatomy, but there is a short section dealing with cells and tissues, and some extremely

inadequate descriptions of certain animal types. The geological history of the vegetable kingdom is dealt with in about half a page of text, but an entire page is devoted to "Lamarckismus und Darwinismus." This being so, it seems a piece of reckless extravagance to have devoted several pages of the section on movement to organisms which do not move. The appetite of the German public for small doses of extremely condensed elementary biology seems to be insatiable. We should like to know to what extent information conveyed in this way is capable of assimilation. It seems as if a considerable amount of previous biological training would be necessary, even for the intelligent reading of such a book as this. It may perhaps be of some use in supplying new points of view to those to whom the actual facts are already more or less familiar.

Heaton's Annual. The Commercial Handbook of Canada and Boards of Trade Register, 1911. Edited by E. Heaton and J. B. Robinson. Pp. 540. (Toronto: Heaton's Agency; London: Simpkin, Marshall, Hamilton, Kent and Co., Ltd.) Price 5*s*.

THE information about Canada which a business-man requires is here arranged in logical sequence. All matter under the head of general information is official, having been collected from the latest Blue Books. The Boards of Trade Register contains descriptions of towns, with notes of opportunities offering for manufacturers, investors, and individuals. Altogether this is a useful work of reference.

Flowers of the Field. By the late Rev. C. A. Johns. Thirty-third edition, entirely revised by G. S. Boulger. Pp. 611+64 coloured plates. (London: Society for Promoting Christian Knowledge, 1911.) Price 7*s*. 6*d*.

NOTHING need be said about the interest and usefulness of a book which has reached its thirty-third edition. In its revised form this popular manual will probably enter on a new lease of life, for it would be difficult to find a more convenient volume for the student of field botany.

The British Isles: Geographical Diagrams and Land Forms, with Questions, Statistics, and Tables. By H. J. Snape. Pp. 64. (London: A. and C. Black, 1911.) Price 1*s*. 6*d*.

MOST teachers expect to find in the text-book of geography they place in the hands of their pupils maps, pictures, and statistics of the kind Mr. Snape has brought together here. In schools where it is difficult to use a magic-lantern, the pictures especially should prove useful. The book is likely to save teachers time and trouble.

Familiar Wild Flowers. Figured and described by F. Edward Hulme. Pp. xviii+184. (London: Cassell and Co., Ltd., 1910.) Price 3*s*. 6*d*.

THIS series of volumes—of which the present is the ninth—with their striking coloured plates, are already widely known and deservedly popular. It is easy with the aid of these books to decide the species and genus of common wild flowers, and to discover the part they may have taken in folk-lore and other literature. We understand this is the concluding volume of the series.

Junior Experimental Science. By W. M. Hooton. Pp. lviii+277. (London: W. B. Clive, 1910.) Price 2*s*. 6*d*.

THIS is the second edition of a book which on its first appearance was reviewed in NATURE for May 16, 1907 (vol. xxvi., p. 51). There do not appear to be any important changes in the volume.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

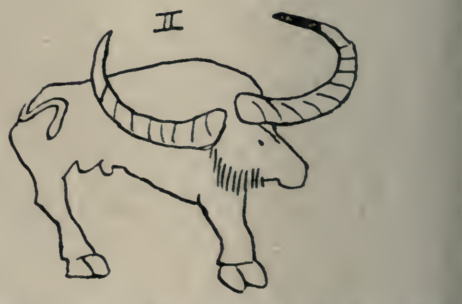
The Extinct Buffalo of Algeria as Drawn by Prehistoric Man.

ONE of my objects in making a tour recently into south-western Algeria and the adjoining region of the Moroccan Sahara was to see the engravings on the rock surfaces, which have lately attracted much attention amongst French men of science, especially those who are more or less connected with the University of Algiers. Quite a number of the sites of these remarkable rock drawings (such as Tiout and Zenaga) can be reached by the long railway which the State has constructed from Oran on the north to Figuig and the Wed Gir in the extreme south of Morocco.

These pictures on the rocks have been mainly studied and illustrated by M. Gautier (Mission Sahara: Le Sahara Algérien), and by M. G. B. Flamand, through the Lyons Society of Anthropology. M. Flamand's great work on the subject, however, is not yet completed for publication.

I

II



Prehistoric drawings of *Bos* (*bubalus*) *antiquus* in South-western Algeria. I, On rock-surface at Ennfous in the Aflou district, east of Géryville. II. At Ksar al Ahmar, near Géryville.

The chief features of interest in these prehistoric drawings will certainly be to zoologists the huge buffalo with enormous horns, which is perhaps the animal most frequently illustrated. I have copied a number of these either from the stones or the photographs of the stones, which may be seen at the University of Algiers or in the Algiers Archæological Museum, and give two of them here.

Of course, the great interest of these drawings is that they come as a valuable supplement to the palæontological discoveries made in the Quaternary and late Tertiary deposits of Algeria. The principal person connected with the discovery and illustration of the vanished fauna of Algeria was the late Prof. A. Pomel, whose works were mostly published between 1893 and 1908. Amongst the discoveries of himself or his predecessors were the remains of a gigantic buffalo—*Bos* (*bubalus*) *antiquus*—a creature

with a superficial resemblance to the Arni buffalo of India, but larger in size and possessing horns exceeding those of the Arni in length, while in its skeleton it evinces a greater relationship to the Cape buffalo. Of course, the fossil remains only give us in their most perfect examples the more or less complete bony core of these horns. We owe to the art of primitive man a better idea of what this armature looked like as a living animal. In full-grown males the horns were marked with annular corrugations, not unlike those still to be seen on the horns of Asiatic buffaloes (there are traces of them also in some of the modern types of Central Africa). There was no considerable development of horn boss on the forehead, and the horns seem to have been flat rather than round. They were set on the skull in such a way that they were not so much directed backwards, as in the Indian buffaloes of to-day, but branched out from the head almost at right angles to the median line of the nose, and in very extravagant developments looked like the figure 3 laid on its side. In some of the drawings there is the indication of the buffalo having developed a considerable fringe of hair along the angle of the lower jaw, in some examples almost a throat mane.

When did this large buffalo become extinct? Some of the authorities I consulted thought not more than two or three thousand years ago. They stated that amongst the engraved rock surfaces that have been photographed there are drawings of this buffalo bearing a pack-saddle. In any case, the drawings I saw myself represented it as being hunted by some form of white man (presumably of Libyan race) wearing a skin garment round the loins and armed with a bow and arrow, or with a spear and javelin, these weapons being either Neolithic or actually within the age of metal.

So far as I know, there is no mention of this buffalo existing in North Africa to be found in any of the Roman writers.

In addition to the buffaloes in these prehistoric drawings, the African elephant is the most striking feature. He is unmistakably delineated with widespread ears, but seldom or never with very big tusks. The fore-foot of these elephants is sometimes girt about by what seems to be a circlet of converging spikes (unless this type of elephant developed bristles on his feet). This recalls in appearance the kind of antelope or buffalo snare which is still in use in Ethiopia and East Central Africa. Other beasts illustrated on the rock incisions of Africa north of the Sahara Desert are the lion, leopard, Mhorr gazelle, Loder's gazelle, and domestic goats and sheep.

Among the remainder of the vanished fauna of Algeria which was apparently coeval with man, but is not to be identified in any prehistoric drawing, was a species of elephant closely allied to that of India, besides the *Elephas antiquus* of Pleistocene Europe. In addition to the buffalo, there was a large wild ox (*Bos opisthonomus*) allied to the aurochs of Europe, and a third form, *Bos ibericus*, apparently nearly related to the Indian zebu, and, if so, in all probability the parent of the modern domestic ox of negro Africa, as well as of types preserved for us in the art of ancient Egypt and of Crete. There was also an eland very like the elands of to-day, and what Prof. Pomel called a nilghai (*Boselaphus rayi*), with longer, more circular horns than those of the existing species; also a gnu, apparently related to the blue gnu of tropical Africa. There were two forms of hippopotamus, one the existing species, and the other a more primitive type with six incisors. Somewhat earlier, perhaps, in period of time was *Cervus pachygenys*, a remarkable form of deer with an exceedingly thick lower jaw, which developed on the outer aspect of its phalanges almost a boss of bone, the purpose or advantage of which does not seem to be very clear. Prof. Pomel also believed that he found in the recent deposits in Algeria a type of Palla antelope, besides an indigenous species of wild camel. As to the modern African elephant, it must have swarmed in Algeria down to the time of the Romans, say two thousand years ago. Its remains are discovered in nearly every watercourse in the northern littoral. The fossil remains on which the late Prof. Pomel's treatises were based can be seen (on application) at the museum of the University of Algiers.

H. H. JOHNSTON.

The Transference of Names in Zoology.

A LETTER on the above subject addressed to NATURE of January 26 by my friend, Dr. Calman, has appeared also in the American journal *Science*. This appeal to the Old World and the New evidently invites discussion. The letter apparently has in mind the man in the street and the natural history specialist, each of whom is to be protected from "moral and intellectual damage," which some applications of the law of priority might inflict upon him.

So far as the general public is concerned, two things should be borne in mind, first, that for popular books on natural history the publisher thinks one Latin name as bad as another, or a great deal worse, and, secondly, that the casual inquirer, when told the technical denomination of an animal, straightway forgetteth what has been told him, be it right or wrong, time-honoured or brand-new. Some handy little names might be kept in stock to gratify these incurious curious persons, as, for example, *Metoponanaphrissontes*, probably applicable to quite a crowd of creatures from annelids to monkeys. Tears seem to mingle with the ink when Dr. Calman tells us that "at present, a writer who mentions Trichechus may be referring either to the walrus or the manatee." Yet what sort of a writer could have the ingenuity to leave it an open question which of the two animals he was discussing? "The great possibility of confusion" to which Dr. Calman refers appears to me to be simply a nightmare, by which he himself is one of the last men in the world to be terrified.

Incidentally, I would beg Dr. Calman and others not to be scared into using Carcinides (Rathbun, 1897) as the generic name of the common shore-crab, assigned to Carcinus by Leach in 1814. It is quite true that Latreille in 1796 named a genus Carcinus in the Amphipoda, but this ought to be considered a *nomen nudum*, since no species was designated as belonging to the genus, and in the course of 115 years no one has fitted the definition to any amphipod in particular.

The conclusion of Dr. Calman's letter reopens a controversy which I will now make one more effort to close.

No crustacean, perhaps, is better known than the common lobster. May I earnestly ask leave here to set forth in full the credentials of its proper scientific name?

1906. *Astacus gammarus*, Stebbing, Victoria Hist. Cornwall, Crustaceans, p. 269.

We have now to consider the significance of these references. There is general agreement at present that the marine lobster and the river crayfish must stand under separate generic names. The question is, Which of the two has a right to that name Astacus, which for many years they enjoyed in common? Miss M. J. Rathbun argues that this was determined in 1810 by Latreille, who in his "Consid. gén. sur les classes des Crustacés," &c., gives a "Table des genres avec l'indication de l'espèce qui leur sert de type," citing for Astacus only *Astacus fluviatilis*. How little Latreille intended by this choice of an illustrative species to strip the lobster of its ancestral title may be inferred from his remark in 1803 that the *astakos* of Aristotle is evidently the marine lobster, and from the fact that still in 1831 he retains lobster and crayfish together in the same genus. Suppose, however, that in such matters a man's intentions are of no consequence, and that only his actions count, the same rule will apply in the case of Borlase, who in 1758 mentions only one species of Astacus, and that the common lobster, thanks to the fact that the river crayfish was not, and seemingly still is not, found in the county of Cornwall. But really the man to whom the restriction of Astacus is due was not Borlase, nor yet Latreille, but William Elford Leach, who in 1815 detached from it Nephrops for the Norway lobster, and in 1819 Potamobius for the river crayfish.

There is talk about lists of *nomina conservanda*. Lists of *exempla vitanda* would be much more to the purpose. Here is a specimen. Leach having previously restricted Astacus to the lobster, Milne Edwards in 1837 unlawfully transfers that name to the crayfish already named Potamobius, and endows the lobster with the new name Homarus, of which it was in no need. In 1852 Dana (U.S. Expl. Exp., vol. xiii., p. 532) follows suit, although acknowledging that "Leach has undoubted priority," but for various fanciful reasons setting that claim aside. He informs us that "in some recent English works the name Potamobius has been substituted for Astacus, and Astacus for Homarus," just as if it were the English works that had committed the crime of substitution, and he winds up his argument by saying, "There seem, therefore, to be reasons enough for rejecting Leach's names, if it is of no weight that they remained for thirty years unrecognised by British authors." Yet John Obadiah Westwood was a British author.

Then Huxley in 1881 ("The Crayfish," third edition, p. 13) tells us that Astacus was retained for both lobster and crayfish until Milne Edwards (in 1837) called the lobster Homarus. "At the present time, therefore," he continues, "while the recognised technical name of the crayfish is *Astacus fluviatilis*, that of the lobster is *Homarus vulgaris*," though he admits that by *astakos* the Greeks, ancient and modern, mean the lobster and not the crayfish, and Huxley himself, while ignoring Leach's Potamobius, accepts and defines (pp. 252, 256) a family Potamobiidæ. In 1888 Spence Bate (*Challenger* Macrura, p. 192) follows in the wake of Dana, with some additional statements, of which my references will supply a sufficient refutation. Thus these distinguished men bolster up one another in wrong-doing, and feebly lament the supposed necessity of doing wrong. At a time when British natural history was at a very low ebb, and natural history at the British Museum had little to be proud of, Leach suddenly threw lustre alike on that institution and on the science of his country. Need we be surprised if John Edward Gray and Adam White and James Sowerby felt the honour of Leach bound up with that of the great museum to which they also belonged? They followed the lead of the famous Westwood in vindicating the claims of Leach. For English-speaking carcinologists on either side of the Atlantic now to aid and abet in the transference of Aristotle's Astakos and Leach's Astacus to a different genus will be unscholarly and unpatriotic, as well as a needless breach in the law of priority.

Thomas R. R. Stebbing.

Tunbridge Wells, February 24.

Time Accuracy in Magnetic Registration.

Some contributions by Dr. Bauer and Mr. Faris in the last volume of *Terrestrial Magnetism* have given rise to a number of letters in this journal concerning the starting times of magnetic disturbances and the accuracy in the determination of time on magnetograms. Mr. Walker (No. 2147, p. 236) points out that the accuracy is augmented by interrupting both curve and base line. This is evident; the beams of light reflected by the various mirrors of the variometers towards the horizontal cylindric lens have, in general, different inclinations, the spots of light on the paper have different heights, so that the interruptions in different traces do not lie on a line perpendicular to the base line. Dr. Krogness (No. 2145, p. 171) desires rapid registering with automatic time marks upon the curve itself, in order to solve the question of simultaneity or non-simultaneity of the abrupt beginnings of magnetic storms for different parts of the globe.

For a number of years, an arrangement answering Dr. Krogness's wishes has been applied at the Meteorological Institute at De Bilt (Netherlands); the method was described for the first time in the Annuary B. for 1905, and recently in *Terrestrial Magnetism* (vol. xv., p. 31, 1910) in a communication concerning the magnetic storm of September 25, 1909. By means of a contact clock, the circuit of a battery is closed for two seconds every minute; the current illuminates a little glow lamp, the filament of which is straight and placed vertically. This filament takes the place of the illuminated slit in the usual arrangement of an Adie magnetograph; its image, about ½ mm. wide, would be formed in the plane of the paper. Just in front of the paper, however, a screen with narrow, horizontal slit is mounted; accordingly, only the light admitted through the slit falls on the paper, and we get a little line or spot about ½ mm. long and ¼ mm. wide. Every minute such a spot is formed; an hour corresponding to 15 mm. of base line, the recorded curve consists of a series of points with a mutual distance of ¼ mm. Another contact lights the glow lamp every twenty minutes for four seconds; this contact falls between two minute-contacts, and is convenient in reading the time. The correction and the rate of the contact clock, and consequently the times of the contacts, are exactly known; the moments of the twenty-minute contacts are 0m., 20m., and 40m. Greenwich mean time.

On quiet or moderately disturbed days the trace looks at first sight as a continuous curve; at times of larger disturbances the points are further apart. With the usual arrangement, in strongly disturbed parts the trace becomes very faint, or is sometimes altogether lost; this drawback may be avoided by taking a wide slit, but then many details in quiet or less disturbed parts of the curve are lost. The new method of registration enables the variations to be followed exactly from minute to minute in all circumstances; it must be granted, however, that some details, *e.g.* rapid oscillations of small period, are not exactly reproduced by this method.

The contacts being given once every minute, the beginning of a disturbance, which, as a rule, falls between two contacts, is known with an accuracy of ½ minute; the uncertainty may be reduced, however, to ¼, ⅙, or $1/2n$ minute by giving the contacts 2, 3, or n times a minute; there is no objection against doing so, only the velocity of registration should be taken greater 2, 3, or n times respectively.

It is evident that the method described shows some analogy with that for seismic registration; here too a time mark is given generally once a minute by a contact clock. These clocks being kept for sale, among others, by the manufacturers of seismographs, the arrangement of magnetic registration in the manner applied at De Bilt is a rather easy matter. For the solution of various problems recently advanced—simultaneity or non-simultaneity of the abrupt beginnings of magnetic storms for different elements, direction and velocity of propagation, and character of disturbances, &c.—the providing of a number of stations, spread over the globe in an appropriate manner, with registering apparatus of the kind described, would undoubtedly yield important data and results.

G. van Dijk.

Meteorological Institute, De Bilt, February 21.

Reflections in Water.

IN the coloured photographs from Egypt, printed in *The Illustrated London News* on February 25, one picture has white clouds and blue sky with their reflection in still water. The image has the appearance of being stronger than the original. The fact is that the blue sky has much more polarised light than the clouds: the cross-polarisation by reflection at the water darkens the sky and scarcely alters the clouds. At the various incidences, by which the different points of the sky reach us, the conditions are altered. Thus the reflected scene is one of greater variety and stronger contrasts. The effect is not due to anything in the photographic process; I was surprised to see such a correct presentation of what I have sometimes observed.

No one could surpass the late Lord Tennyson in his love for noting various moods of nature, but perhaps the habit is more frequent with great masters of language in France than with us. Pierre Loti abounds with such passages as "Avec cette sonorité particulière que les cloches prennent pendant les nuits tranquilles des printemps." Rostand devotes the opening verses of "Chantecler" to the varied powers of sunlight: the sinking sun, for instance, which chooses

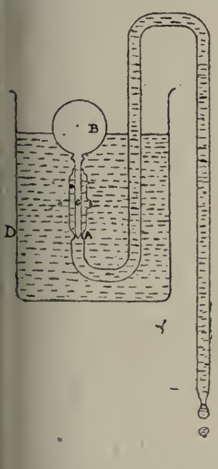
L'humble vitre d'une fenêtre
Pour lancer son dernier adieu.

There are two marked forms in which we often see this. Sometimes it is difficult to believe that there is not a fierce red fire raging in a distant house. At other times, with a higher and a whiter sun, a house on the hill may reflect the sun to us, surrounded with brilliant coloured halos. I suppose that dust upon the window diffracts the light, as do the dust plates of Fraunhofer.

The College, Winchester. W. B. CROFT.

A Self-regulating Siphon.

IN a large number of laboratory experiments it is necessary to keep a continuous flow of water through a vessel in which the level must remain constant. Some sort of self-regulating siphon is a great convenience for this purpose, and that here described is both simple in construction and very efficient in use.



The **U**-tube, bent out of ordinary quarter-inch quill tubing, as shown in the sketch, is narrowed at the point A, and the small piece of glass rod, C, is drawn out so as to fit this constriction. The bulb B, sealed on to the top of this rod, floats on the surface of the water. The **U**-tube must be so fixed that when the water is at the desired level the rod just fits into A, and so closes the exit. If the level of water in the vessel D rises at all, the bulb is raised, and the excess of water flows out through the siphon.

W. H. TAIT.

King Edward VI.'s High School, Birmingham.

The Plumage Bill.

THE statement has been widely circulated by a section of the Chamber of Commerce interested in the feather trade that the aigrettes or ospreys which are now worn are, for the most part, the moulted plumes collected after the breeding season. Long ago Prof. Alfred Newton exposed this statement. He emphatically stated that "cast" feathers do not find their way into the market, and added, "I should doubt whether cast feathers have any real value at all in the plume trade," his belief being that no one concerned in it would look at them. Again, Mr. W. H. Hudson wrote:—"Each bird produces only a small number of these valued feathers, and when he sheds them he does not shed them all together in some spot where a feather-hunter will be sure to find them. He drops them one by one at odd times, some falling in the water where he fishes, some among the trees and rushes where he roosts, and some are shed when he is on the wing going from place to place."

Sir E. Ray Lankester, Mr. W. P. Pycraft, and Mr. James Buckland testify to the truth of the foregoing. Sir E. Ray Lankester says:—"It is always the parent bird, slain at the breeding season, which supplies 'ospreys' for women's hats and bonnets. . . . I am quite tired of assuring the public of the facts of the matter."

In introducing his Bill to prohibit the sale, hire, or exchange of the aigrette and other plumes, Mr. Percy Alden stated that last year some thousands of ounces of these plumes were offered for sale at Mincing Lane. It is estimated that this amount represents the breeding plumes of about 20,000 parent birds, the fledglings of which were probably left to die of starvation. Legislation is the only means of coping with this insensate massacre. JOSEPH COLLINSON.

York House, Portugal Street, W.C., February 28.

Edward Blyth and the Theory of Natural Selection.

WITH reference to Mr. H. M. Vickers's letter in NATURE of February 16, I may perhaps mention that the Edward Blyth who edited Gilbert White's "Selborne" in 1836, a reissue of which was made in 1858, dated his "advertisement," or preface, from "Lower Tooting, November, 1836." Blyth's bird notes to this edition are extensive, but the other portions of the book are very free from annotation. EDWARD A. MARTIN.

285 Holmesdale Road, South Norwood, S.E.

Cat Playing with Shadow.

CAN any correspondent of NATURE recall a case of a cat playing with a shadow?

I know of a cat—a blue Persian—which appears to wait until the morning sun throws the shadow of a cage-bird on the wall of a room, and then seems to play at catching the shadow of the bird as it moves about.

H. S. G.

22 Kensington Park Gardens, W.

THE A-KAMBA OF BRITISH EAST AFRICA.[1]

MR. HOBLEY has again put ethnologists in his debt by giving another series of observations on certain tribes of British East Africa. His monograph on "Eastern Uganda: an Ethnological Survey," published by the Royal Anthropological Institute in 1902 was followed in 1903 by a valuable paper, "Anthropological Studies in Kavirondo and Nandi," in the *Journal* of the Institute. In the present volume he deals mainly with the A-Kamba, who inhabit a large area south and south-east of Mount Kenia, and about whom we have hitherto had extremely little information, with the exception of a capital general and comparative ethnographical account by J. M. Hildebrandt in the *Zeitschrift für Ethnologie*, Bd. x., 1878, p. 347. A small book containing vocabularies of the Kamba and Kikuyu languages, compiled by Mrs. Hinde, was published by the Cambridge University Press in 1904, but no details are given about either people.

The A-Kamba are probably the purest representatives of the Bantu stock in British East Africa; they are a sturdy people, the males being about 5 feet 6 inches in height. The average cephalic index of ten men is 78·6, while that of two skulls is 74. The nose is platyrhine. Two general types of head are noticeable, one "with very wide massive jaws, curved sides, and tapering towards the forehead, a very coarse negroid type, and the other is, comparatively speaking, a more intellectual type, with a wider fore-

[1] "Ethnology of A-Kamba and other East African Tribes." By C. W. Hobley, C.M.G. Pp. xvi+174. (Cambridge: University Press, 1910.) Price 7s. 6d. net.

head and narrower in the region of the jaws; the chiefs generally belong to the latter type. It appears to be impossible to discover any reason for this variation." Periodically numbers of the younger people are seized by a peculiar form of hysteria (resembling the so-called arctic hysteria), and the sight of a hat or cap, or sometimes of a dog, causes the patient to fall into convulsions, until the obnoxious object is removed from sight. The numerical proportion of the sexes is equal, and polygyny is fast dying out. The A-Kamba are the only people in East Africa who chip the upper incisor teeth to a point; filing or chipping the teeth is generally supposed to be associated with cannibalism, but so far as can be ascertained no such custom exists or has existed among the A-Kamba. The ornaments, clothing, implements, arts and crafts of the people are succinctly described, but the most valuable portion of the book is that dealing with the social and religious aspects of native life. The birth, marriage, and death customs are recorded, but those connected with puberty are of greater interest. Circumcision is performed when the child is about four or five years old; this is only a small affair, but more important is an initiation ceremony, which lasts for several days, at which several hundred young people are often present; the boys and girls are divided into batches of ten or fifteen, with a fully initiated youth or girl in charge of each batch. It is the duty of these tutors to teach their pupils their duties in life; they also cut pictographs on sticks, the meaning of which the neophytes have to discover. Some two months later the youths only undergo a ceremony of a very secret character in the woods; in the darkness of the night a weird booming roar is heard, and the youths sit and shudder with fright. This is said to be caused by a fearsome beast, which on the third day is supposed to be killed and its flesh eaten by the novitiates. Very little is known about this ceremony, which is evidently one of great antiquity and interest.

FIG. 1.—Pictographs cut on a stick representing a star; moon; arrow; black, red-legged millipede; python, the dots represent the spots on the reptile's skin; spider; tortoise; lizard; wooden jar for carrying honey. From "Ethnology of A-Kamba and other East African Tribes."

FIG. 2.—Matungi, chief of the Mogogodo tribe. From "Ethnology of A-Kamba and other East African Tribes."

The second part of the book contains some valuable notes upon a few other tribes; of especial importance are the notes on the social organisation of the Masai, among whom a geographical grouping is replacing the older clan grouping; the marks branded on the cattle correspond to the latter, while the designs on the shields have a territorial significance. Mr. Hobley directs attention to the promising field for research, not only in the ethnology but in the archæology of British East Africa. His little book, which is extremely well illustrated, serves to emphasise how much more there is to be done; for example, he has discovered a new small pastoral tribe, the Mogogodo, on the foothills on the north side of Kenia, who possess a remarkable language, and features that remind one of certain ancient Egyptians. In a prefatory note, Prof. Ridgeway strongly endorses the remarks of Mr. Hobley on the importance of Government officials having a preliminary training in anthropology.

A. C. HADDON.

THE TOKYO IMPERIAL UNIVERSITY.

THE peoples of the West for a long time had the impression that while the Japanese had great artistic ability and could imitate the productions of other countries, they had little or no originality. Notwithstanding all that they have accomplished during the past forty years or so, both in the arts of peace and war, that impression still prevails to a considerable extent, and we frequently hear opinions which do not do justice to their general ability, their trustworthiness, or their originality. It would take us too far afield if we attempted to disprove those opinions from what the Japanese have accomplished, but a perusal of the reports of the Minister of State for Education and of the calendar of Tokyo Imperial University shows that the developments which have taken place in Japan in recent times are not the superficial veneers which some people would have us believe they are, but, on the contrary, that they have been made on a solid foundation of education.

The annual report of the Minister of State for Education is a most interesting document, and shows that during the time which we have mentioned every department of education which is necessary to train men and women for all the duties of a modern State has been very fully developed. Elementary schools are to be found in every part of the country, and secondary schools have been established in the more important centres of population, while a great variety of special and technical schools, fit for all the functions required under the new conditions, which are the result of the adoption of Western science and habits of life.

At the head of all these educational institutions stand the Universities of Tokyo and Kyoto, the calendar of the former of which has just come to hand, and a perusal of it will be useful to all who are interested in education in this country, as in some respects it shows a width of view and a completeness of arrangement which are not always observable in universities in this country. The University of Tokyo began in a very small way, and its development is sketched in the interesting historical summary which serves as an introduction to the calendar. At a comparatively early stage it had four departments of study, namely, those of law, science, literature, and medicine, and in 1886 the Kobu-Daigakko or Imperial College of Engineering, became a college in the university. Readers of Nature of between thirty and forty years ago will remember this as the college associated with the names of Dr. Henry Dyer and Dr. Edward Divers, its first and second principals, and of Profs. Ayrton, Perry, Milne, and other graduates of British universities.

The university now consists of six colleges and one university hall. The colleges are those of law, medicine, engineering, literature, science, and agriculture. The College of Law includes the two courses of law and politics, with thirty-four professorial chairs. The College of Medicine includes the two courses of medicine and pharmacy, with thirty-one professorial chairs. In connection with this college there is a course of State medicine. The College of Engineering includes the nine courses of civil engineering, mechanical engineering, naval architecture, technology of arms, electrical engineering, architecture, applied chemistry, technology of explosives; and mining and metallurgy, with thirty-two professorial chairs. The College of Literature includes the three courses of philosophy, history, and literature, with twenty-four professorial chairs. The College of Science includes the nine courses of mathematics, astronomy, theoretical physics, practical physics, chemistry, zoology, botany, geology, and mineralogy, with twenty-five professorial chairs. The College of Agriculture includes the four courses of agriculture, agricultural, chemistry, forestry, and veterinary medicine, with thirty professorial chairs. For the training of practical farmers, subsidiary courses of agriculture, forestry, and veterinary medicine are provided in connection with the College of Agriculture.

The university is well equipped with all the appliances required for the practical teaching of the various subjects. It has a very good library, containing a large number of all the more modern books required in university study. Hospitals are connected with the College of Medicine. An Institute of Historical Compilation is a part of the College of Literature connected with the College of Science are the Tokyo Astronomical Observatory, the Botanical Garden, the Seismological Observatory, and the Marine Laboratory. Forests, experimental farms, veterinary hospitals, and the Institute for the Training of Agricultural School Teachers are connected with the College of Agriculture. There are many laboratories and museums in connection with the Colleges of Medicine, Engineering, Science, and Agriculture.

The total number of students is between five and six thousand, and of graduates in one year nearly nine hundred. The record of the occupations of the graduates after they have left the university shows that they have taken up practical work connected with the special department which they had selected as students. A large proportion become Government officials, lawyers, engineers, medical practitioners, and teachers. There are two private institutions in Tokyo of university rank, the Keio Gijiku and the Waseda Universities, each of which has a large number of students, the majority of whom enter private services, as distinguished from the students of the Imperial University, a large proportion of whom become Government officials.

That the students of the university do not simply absorb Western learning and apply it to practical purposes is shown by the long list of papers which is printed at the end of the calendar, giving the contents of the *Journals* of the Medical, Engineering, Science, and Agricultural Colleges, and the bulletins of the Engineering and Agricultural Colleges. Those who have had the opportunity of perusing these publications will admit that they will bear very favourable comparison with those of similar publications in any other country, and those who have the pleasure of knowing the professors personally will admit that they are men of ability, learning, and character, of whom any learned institution in the world would have no reason to be ashamed.

A survey of the results of education on the affairs of the nation shows convincingly and conclusively the intimate relation that exists between the provision made by a nation for the higher education of its people and the position taken by that nation in the ceaseless competition between the great countries of the world. After a searching comparison between the facilities for university education in this country, on one hand, and in the United States and Germany on the other, Sir Norman Lockyer was justified in saying in his presidential address at the British Association meeting at Southport:—

"But even more wonderful than these examples is the 'intellectual effort' made by Japan, not after a war, but to prepare for one. The question is, Shall we wait for a disaster and then imitate Prussia and France, or shall we follow Japan and thoroughly prepare by 'intellectual effort' for the industrial struggle which lies before us?"

H. D.

FIFTH MIGRATION REPORT OF THE BRITISH ORNITHOLOGISTS CLUB.[1]

We have before us the fifth annual report of the migration committee of the British Ornithologists Club, containing the data with regard to the arrival and dispersal within England and Wales of our common migratory birds during the autumn of 1908 and the spring and early summer of 1909, scheduled and tabulated as in former years. The report, which is longer than any of its predecessors, summarises a vast number of observations sent in by numerous voluntary observers, and by the keepers of the coastwise lighthouses and lightships. These data, compiled with an infinitude of labour and care, will always retain their value as a contribution to our knowledge of the movements of the species dealt with within the narrow limits of the area of reference. Even such apparently dry details—composed solely of names and figures—present (among those, for instance, sent in from the lonely sea-girt stations dotting our shores from The Hanois to St. Abbs Head) an interesting and fascinating picture of that wild, inexplicable rush of our feathered friends in a commingled horde fleeing as from judgment to come, which every autumn blindly compels to the southward, but to what latitudes we know not yet for certain.

The dates of the movements of the scheduled birds tabulated on the maps afford us again the satisfaction of following the sure and happy return of our

[1] Bulletin of the British Ornithologists Club. Edited by W. R. Ogilvie-Grant. Vol. xxvi., Report on the Immigrations of Summer Residents in the Spring of 1909; also Notes on the Migratory Movements and Records received from Lighthouses and Light-vessels during the Autumn of 1908. By the Committee appointed by the British Ornithologists Club. (London: Witherby and Co., 1910.)

summer songsters as they hasten hard after the northing sun. The tale each map is intended to tell is made evident on its face by a system of signs, but they are intelligible, however, only to those acquainted with the earlier reports. As the student may not always have these at hand, it would be advantageous and would save some "language," if the editor would, as already suggested in Nature of May 26, have the interpretation of the hieroglyphical brackets inserted in the preface or cause explanatory legends to be attached to each map; for the signs have not invariably the same meaning in all of them, while occasionally new signs are introduced without explanation, such as the hexagons and octagons which are used in the present report.

There is considerable inconsistency also in the plottings of the observations. In some schedules the earliest arrivals, even if solitary, are entered, but not invariably: in others, movements mentioned in the chronological summary, which appear to us to be of importance, are ignored for no obvious reason. In the diary of the swallow, for instance, the summary includes a large number of records for May, yet the whole of them (with the exception of those for "2," "7–14," and "3," on the south coast), although numerous and apparently as important as those of March and April, are entirely unscheduled. So far, also, as appears from the map, there was in 1909 only a single swallow immigration, yet the summary alludes to several, and in previous years as many as five are separately mapped. In the section entitled "Unscheduled Birds," sixty-six birds are recorded, and are listed in many cases with fuller details than those given for the scheduled species. It would be an advantage to those studying the evidence, we think, if, in future reports, both scheduled and unscheduled birds were incorporated in one list, the latter in less prominent type, if need be. There is as much to be learned from the one set as from the other. It would, likewise, be important and very interesting to have lighthouse records for the arriving as well as for the departing bird-streams, and to know if the spring flocks are composed of as mixed assemblages of species as those of the autumn. It would be worth trying also to ascertain whether, if this be not the case on arrival, it be so as they start from their winter quarters.

Those who have followed this inquiry will remember that the reports which the committee have presented during the last five years are but fuller continuations of the investigations carried on for so many years by a British Association committee. The present committee, in their second report, hoped "that in a few years results of considerable value may be obtained." Many ornithologists are of opinion that if these elaborate and costly compilations are ever to contribute to the solution of the migration mystery some results ought by now to be showing on the surface. Yet if we search through the four last reports, we fail to discover any fact of real significance which is not to be found in the first. The dates of the arrival and departure of our migrants are seen to vary slightly from year to year; the wave may be larger or smaller, and the species which make their port of entry in one year east of the Isle of Wight may choose one to west of it in other years. But of what importance is this information to the problem? Five years ago it was believed that the methods adopted by the committee would probably provide material for valuable generalisations. Year after year passes, and our disappointment grows that we seem no "forarder" in our quest. It is becoming daily clearer that the area of observation is far too limited, for the land-patch of England and Wales is no more to the wide area covered by migrants than Trafalgar Square is to the county of Middlesex. The complex problems—the cause of the impulse, whether it originates within or outside the birds, and whether it affects all species, though in different degrees: how the young birds (if in autumn they really—which is very questionable—precede their parents into uncharted space) find their way, and other such questions, cannot be solved by tabulating the momentary vision of a passing bird in association with local meteorological or other conditions which it encounters by chance *en route*, except over a wider area than these reports deal with, and by taking many other influences into consideration.

We firmly believe that no contributions of real value to this inquiry can be attained, if they ever are to be attained, except by the united international action of ornithological societies in marking vast numbers of parents as well as nestlings in their breeding localities, of "the thousands" also of those that are temporarily dazed at lighthouses, and of northern species while in winter quarters in various regions of Africa, and of southern Asia and America. Only thus are we likely to discover what awakens the migratory impulse at a particular date, whether meteorological changes, deficiency of food supply, decrease of sun-heat and light, or other external causes, or whether none of these have any influence, and perhaps solely an inherited periodical brain-storm impels them to the road. Only by the capture of birds, numerously marked at their nesting-places in northern and in their winter quarters in southern latitudes, can their routes, out and home, be plotted and dated with any approach to exactitude. Such an inquiry must needs be protracted even with united world-wide interaction; but it seems more hopeful than any other. Moreover, it is urgent, and ought to be commenced at once. The mystery of migration may, nevertheless, elude the best efforts of our generation towards its solution.

JOHAN GADOLIN.[1]

JOHAN GADOLIN, one of the most distinguished of Finnish men of science, occupies a well-defined position in the history of chemistry. He was a pupil of Bergman, a friend of Scheele, and the forerunner of Berzelius. He served as a connecting link, as it were, in the new departure of the science as initiated by the workers at Upsala, and as so splendidly furthered by the secretary of the Stockholm Academy. Gadolin's scientific activity was, in fact, concentrated within the two decades which elapsed between the death of Scheele and the coming of Berzelius, and his labours worthily upheld the traditions of the Scandinavian school.

Gadolin came of a family which had long been associated with learning and scholarship in Finland. He was born June 5, 1760, at Åbo, then the capital of Finland, and the seat of its university. His father, Jacob Gadolin, was formerly professor of physic, afterwards of theology, and ultimately Bishop of Åbo. His maternal grandfather, Johan Browallius, a contemporary and friend of Linné, had also served as professor of physic, and, like his son-in-law, was likewise made a bishop. After passing through the High School of his native town, the young Gadolin attended the lectures of Pehr Adrian Gadd, the first to hold a chair of chemistry in the Finnish University. Attracted by the fame of Torbern Bergman, then one of the foremost leaders of chemical science in northern Europe, he passed over to Upsala, where he remained four years. During that time he became known to Scheele, and was on terms of intimate

[1] Johan Gadolin, 1760–1852. In Memoriam. Wissenschaftliche Abhandlugen Johan Gadolins in Auswaht. Herausgegeben von Edv. Hjelt und Robt. Tigerstedt. Pp. cii+287. (Leipzig: S. Hirzel, n.d.) Price 12 marks.

friendship with him during the few short years of life that were left to him.

Gadolin was the most distinguished of Bergman's pupils. Under him he began the metallurgical and mineralogical inquiries with which his name is associated. At Upsala, too, he commenced his work on specific heat, which he subsequently published at Åbo in 1784. On the death of Bergman, he was a candidate for the chair at Upsala, but Afzelius was chosen, whereupon Gadolin returned to Finland, and in 1785 was made professor extraordinarius at the University of Åbo. The duties of his office left him, however, ample leisure, part of which he occupied in travel in Germany, Holland, and England. He established a literary connection with Lorenz Crell, which led to frequent communications to the *Annalen* which Crell edited. Whilst in London he published a memoir on the analysis of iron ores by wet methods, in which he gave the first suggestion of a method of volumetric analysis, and in conjunction with Crawford he undertook a series of determinations of the latent and specific heat of ice. Passing over to Ireland, he made the acquaintance of Kirwan, with whom he subsequently corresponded on mineralogical matters.

Gadolin was early attracted to the work of the French School of Chemistry, and made known the new doctrine to northern Europe. On his return to Åbo in 1789 he adopted the new chemistry as a feature of his teaching. In 1797, on Gadd's death, he became ordinary professor of chemistry, holding the chair until 1822, when he retired. Phlogistonism died hard in Sweden, but Gadolin's handbook, which he published in the Swedish language in 1798, did much to kill it. The most fruitful period of Gadolin's scientific activity is comprised between the years 1788 and 1803.

It was Gadolin who first made known the existence of a new earth in a black mineral from Ytterby, in Sweden, which Ekeberg subsequently termed *Yttria-earth,* the first discovered member of that numerous group of bodies we term the rare earths. The mineral itself became known as Gadolinite. A hundred years later Marignac and Lecoq de Boisbaudran found a new element in Samarskite, which they named *Gadolinium,* in honour of the discoverer of the first of this series of substances.

The great fire of 1827, which practically destroyed Åbo, and with it the university buildings and the whole of his mineral collections, terminated Gadolin's scientific career. The site of the university was moved to Helsingfors, and Gadolin retired to the country, where he died on August 15, 1852, at the age of ninety-two.

In the handsome quarto volume before us Prof. Hjelt and his collaborator have put together a very complete account of Gadolin's career and of his services to science. This is followed by copious extracts from his correspondence, some details of his courses of university lectures, and a selection of his more important memoirs, and the whole concludes with a list of his contemporaries, more particularly of those associated with him as academic colleagues, coworkers in science, or as literary correspondents. The chapter on Gadolin's scientific activity contains an admirable critical account of his relation to his period and of the part he played in connection with the downfall of phlogistonism. It also contains a full and discriminating analysis of his more important memoirs, viz., on specific heat, on iron analysis, and on his detection of the first member of the series of rare earths. The short acount of his system of teaching is largely made up of extracts from the manuscripts of his lectures. They are especially rich in historical references and throw interesting sidelights on his period.

T. E. T.

NOTES.

We notice with deep regret the announcement of the death, in his fifty-ninth year, of Prof. J. H. van 't Hoff, honorary professor of general chemistry in the University of Berlin, on February 1, at Steglitz, near Berlin.

The nineteenth "James Forrest" lecture of the Institution of Civil Engineers will be delivered on Wednesday, June 28, by Dr. F. H. Hatch, his subject being "The Past, Present, and Future of Mining in the Transvaal."

The president of the Royal Society and the members of the General Board of the National Physical Laboratory will meet at the laboratory on Friday, March 17, for the annual visitation, when the various departments will be on view.

Prof. H. E. Armstrong, F.R.S., has been nominated the delegate of the Royal Institution at the celebration of the centenary of the Royal Frederick University of Christiania, and Sir James Crichton-Browne, F.R.S., as delegate at the celebration of the 500th anniversary of the University of St. Andrews.

Lieut.-Colonel David Prain, F.R.S., director of the Royal Botanic Gardens, Kew, has been elected a member of the Athenæum Club under the provisions of the rule which empowers the annual election by the committee of a certain number of persons "of distinguished eminence in science, literature, the arts, or for public services."

It is announced in the *Revue scientifique* that M. Fauvel has offered 30,000 francs for the construction of an annexe to the laboratory of the National Museum of Natural History in Paris.

The death is announced, at sixty-eight years of age, of Mr. John Sime, C.I.E., late Director of Public Instruction in the Punjab and Under-Secretary to the Punjab Government in the Education Department.

We regret to notice that Mr. E. E. Wilson, formerly an assistant in the radiography department of the London Hospital, died on March 2 as the result of disease contracted by frequent exposure to Röntgen rays.

The Easter excursion of the Geologists' Association will be to St. David's district, South Wales, and will extend from April 13 to April 22. The excursion directors are Mr. J. F. N. Green and Prof. O. T. Jones, and the excursion secretary Mr. A. L. Leach, Giltar, Shrewsbury Lane, Plumstead, S.E.

A conference of members of the Museums Association and others interested in museums will be held at Belle Vue and Bankfield Museums on Saturday, April 8, for the purpose of discussing subjects of interest to those concerned in the work of museums, art galleries, and kindred institutions. Anyone proposing to attend the conference should communicate with Mr. H. Ling Roth, Briarfield, Shibden, Halifax.

Dr. John W. Harshberger, assistant professor of botany in the University of Pennsylvania, has just returned from an expedition in the Everglades of southern Florida, during which he collected several plants previously unknown to science. The Everglades themselves, he reports, are fast passing away through continual drainage, and their vegetation is likely soon to become extinct.

We learn from *Science* that the U.S. Senate has passed the Weeks Bill providing for the establishment of a forest reserve in the Appalachian Mountains. The Bill is applicable from Maine to the Gulf of Mexico, on the eastern

seaboard. The Bill gives the consent of Congress to the States to enter into an agreement among themselves for the purpose of conserving the forests and water supply of each, and grants 40,000*l*. to enable the Secretary of Agriculture to cooperate with such States in giving fire protection. In addition, the Bill appropriates 200,000*l*. for one year, and not more than 400,000*l*. for each year thereafter, until 1915, for surveys, examinations, and acquirement of lands located at the headwaters of streams which are being or may be developed for navigable purposes.

A FLIGHT from Paris to the crest of the Puy de Dôme was accomplished by M. Eugène Renaux on a Maurice Farman biplane with a passenger on March 7. The distance is 210 miles, and the journey was made to the crest of the Puy de Dôme, 4000 feet high, in 5h. 11m., after one landing. This is the fourth noteworthy aëroplane flight of the present year, the others being :—January 30, Mr. McCurdy, the Canadian aviator, flew over-sea from Key West (Florida) to within ten miles of Havana, in the island of Cuba; February 1 and February 2, Captain Bellanger flew from Paris to Pau, *via* Bordeaux, a distance of nearly 500 miles; March 5, Lieut. Bague flew 140 miles over-sea from Nice almost to the Italian coast. Referring to these flights, *The Morning Post* says :—" These flying achievements, viewed in regard to the lengthy periods over which they were sustained, the precision with which they were executed, and the fact that in each case the aviator had a definite goal which he succeeded—or all but succeeded—in reaching, place the art of aviation in a position, as concerns its practical usefulness, which it would have been all but impossible to have foreseen only a year ago."

THE following are among the lecture arrangements at the Royal Institution after Easter :—Prof. F. W. Mott, two lectures on the brain and the hand; Prof. W. W. Watts, two lectures on (1) the ancient volcano of Charnwood Forest (Leicestershire), (2) Charnwood Forest and its fossil landscape; Prof. R. W. Wood, three lectures on the optical properties of metallic vapours; Dr. W. N. Shaw, two lectures on air and the flying machine : (1) the structure of the atmosphere and the texture of air currents, (2) conditions of safety for floaters and fliers; Mr. T. Thorne-Baker, two lectures on (1) changes effected by light, (2) practical progress in wireless telegraphy; Mr. W. P. Pycraft, two lectures on phases of bird life : (1) flight, (2) migration. The Friday evening meetings will be resumed on April 28, when a discourse will be given by Prof. W. M. Flinders Petrie on the revolutions of civilisation. Succeeding discourses will probably be given by Prof. Martin O. Forster, Prof. W. Stirling, Prof. R. W. Wood, Prof. Gilbert Murray, Commendatore G. Marconi, and Prof. Svante Arrhenius, among others.

THE first Universal Races Congress will be held on July 26–29 in the central building of the University of London. The object of the congress will be to discuss, in the light of modern knowledge and the modern conscience, the general relations subsisting between the peoples of the West and those of the East, between so-called white and so-called coloured peoples, with the view of encouraging between them a fuller understanding, the most friendly feelings, and a heartier cooperation. The following is the programme for the eight half-day sessions :—(1) fundamental considerations—meaning of race, tribe, nation; (2–3) general conditions of progress; (3*a*) peaceful contact between civilisations; (4) special problems in inter-racial economics; (5–6) the modern conscience in relation to racial questions; (7–8) positive suggestions for promoting inter-racial friendliness. It is proposed to hold in connection with the congress an exhibition of books, documents, photographs of the highest human types, skulls, charts, &c. The exhibition is under the direction of Dr. A. C. Haddon, F.R.S., and promises to be of wide interest. A prospectus will be sent free of charge on application to the honorary secretary of the congress, Mr. G. Spiller, 63 South Hill Park, Hampstead, London.

MR. L. PEARSALL SMITH writes to *The Times* to suggest that another term, such as " halcyon "—used as a substitute—should be adopted in the place of " anti-cyclone," as this word is said not to convey the connotation of calm and pleasant weather conditions. " While popular speech," he remarks, " has been able to adopt ' cyclone,' it has found, as we might expect from its form, ' anti-cyclone ' unsuited for its purpose." The unfortunate thing is that popular speech, as expressed in the daily Press, calls a storm or any unusual atmospheric disturbance a cyclone, whereas it is nothing of the kind. What Mr. Smith proposes, therefore, is that the exact terms of meteorological science shall be modified to adapt them to the indefinite and often incorrect expressions of popular language. For the sake of the preservation of precision in scientific nomenclature, it is worth while to give in this connection a quotation from a publication of the U.S. Weather Bureau, issued many years ago :—" The terms ' cyclone ' and ' anti-cyclone ' do not describe phenomena that can be observed by one observer at a single station; they should, therefore, not be used in the description of local phenomena; they represent generalisations based upon the charting and study of winds and clouds observed at many stations, and should only be used when the nature of the rotation of the wind has been clearly demonstrated or can be safely inferred."

A SUMMARY of the temperature, rainfall, and bright sunshine in the United Kingdom for the past winter is given by the Meteorological Office in its last issue of the Weekly Weather Report. The mean temperature was slightly in excess of the average over the entire kingdom, but the difference was nowhere large. At Greenwich the mean for the three winter months, December to February, was 1·7° below the normal, but December is the only month where the departure from the average was considerable, amounting to an excess of 5°. The Midland counties is the only district in which the sheltered thermometer touched 60°, whilst the minima in the several districts fell below 20° everywhere except in the Channel Islands. The aggregate winter rainfall was deficient except in the north and west of Scotland and in the east and north-west of England. The greatest deficiency is 2·64 inches in the south of Ireland, and 2·22 inches in the Channel Islands. The largest aggregate rainfall for the three months is 17·37 inches in the north of Scotland, and the least 4·30 inches in the north-east of England. There was an excess of rain during the winter at Greenwich, due entirely to the heavy rains in December. The rainy days were in fair agreement with the average, the maximum number being 73 in the north of Scotland, and the minimum 46 in the north-east of England. The duration of bright sunshine was generally in fair agreement with the average over the whole kingdom, the records for England showing a slight excess. The maximum duration of sunshine is 209 hours in the Channel Islands, the minimum 103 in the north of Scotland.

WE learn from the Wellington (N.Z.) *Evening Post* of December 7, 1910, that the New Zealand Government has voted 50*l*. or 100*l*. towards the cost of explosives for rain-

making experiments to be made at Oamaru and adjacent drought-stricken parts. It has been shown that such experiments are a useless expenditure of money, and (as stated in the article) have been condemned by the best meteorologists of Europe and America. *Symons's Meteorological Magazine* (July–September, 1908) contains a careful report by Mr. D. C. Bates, who was ordered to watch and report upon rain-making experiments previously carried out in the same district. He states that "the explosions had apparently no more effect on the vast expanse of the air than would the striking of a match in a room." In a lecture printed in *Popular Science Monthly* for January last, Prof. C. Abbe, one of our leading authorities on meteorology, states, in connection with laboratory experiments on the formation of clouds and rain:—"I think you will see that the firing of cannon or dynamite in order to make a great noise is not likely to form rain, and, in fact, cannot possibly bring it down." And further, with reference to the cannon used in Italy to send vortex rings of air into the clouds, he says:—"We have no evidence that they ever reach them, or that they could have any effect if they did so. . . . I regret to think of so many thousands of farmers wasting time and money on this delusion"; and with these opinions we entirely concur. The situation was saved in the present instance by rain having fallen before the explosions took place.

THE thirty-third annual general meeting of the Institute of Chemistry was held on March 1. Dr. George Beilby, F.R.S., the president, occupied the chair, and delivered an address, in which, after referring to the losses of the institute by death, mentioning especially Prof. Campbell Brown, Mr. Michael Carteighe, and Mr. Oscar Guttman, he dealt with the progress and work of the institute. The membership continues steadily to increase, notwithstanding the high standard of the examinations, while the position of the institute as an organisation existing for public service never stood so high as at the present time. The council has under consideration the institution of a series of lectures, the object of which will be to bridge over the gap between academic training and practice. Without depreciating the value of a broad scientific education, it is realised that students entirely trained in an academic atmosphere miss some of the advantages of the old system of private pupilage in the laboratories of practising fellows or in works. This loss is met in some instances by students preparing for the final examination in such laboratories, but there is a need for a means of introducing something analogous to the clinical instruction afforded to medical students. It is proposed, therefore, to ask fellows having expert knowledge to give lectures which will give students an insight into the actual work of the chemist, whether engaged in the application of his science to commerce and industry or to the scientific control of the affairs of daily life. Prof. R. Meldola, in moving a vote of thanks to the president for his address, said it would give him much pleasure to see the institute take an active part in the education of chemists, and he cordially supported the new departure as to the institution of the proposed lectures, which will make the student realise more fully the value of the practical side of his subject.

IN *The Times* of March 4 there appeared a further article upon the subject of the spread of plague. Dealing, first, with the disease amongst rodents in East Anglia, the writer refers to the rat investigation recently carried out at Ipswich under the auspices of the Local Government Board. This inquiry lasted for about six weeks, during the course of which about 6000 animals were examined. These rats were not drawn from the area already known to be infected, but from a fairly extensive tract of country on its outskirts. No report has yet appeared, but it is believed that few, if any, plague-rats were found. This result, although apparently reassuring, does not affect the main question. The investigation was carried out during the off-plague season, and at the time when fewest rat-fleas are found. Similar inquiries carried out in India and elsewhere show that it is dangerous to conclude that plague has disappeared from an infected area because no plague-rats are found. It is thereafter desirable that the investigations should be repeated in autumn, and at intervals during the next two or three years. In the meantime, the campaign of rat extermination should be prosecuted with undiminished vigour. Reference is made to the proposal of the War Office to hold extensive manœuvres in Essex. While the possibility of infection among the troops must be considered remote, yet it cannot be said that the establishment of large standing camps is altogether free from risk. Turning next to the question of plague manifestations in other parts of the world, the writer of the article gives some important particulars concerning the occurrence of the pneumonic form of the disease during recent years. These show that a relatively large proportion of such cases occur in temperate climates. Very little is at present known about pneumonic plague, and there are often difficulties in its diagnosis. It is not unlikely that much valuable information may be obtained by a study of the present outburst in Manchuria. No explanation can be afforded for the mysterious disappearance of plague at the beginning of the eighteenth century, or for its equally mysterious reawakening in the Chinese province of Yunnan in the 'seventies of last century. Since the year 1896 it has caused a terrible loss of life in India, and spasmodic cases have occurred in every continent. It has been argued that the Manchurian outbreak suggests an increasing intensity in the violence of plague infection, the consequences of which will presently be universally manifest. Whether or not this be the case, there is ample justification for the statement that the outlook is not hopeful in places where the rodents are infected. Where infection exists there is always danger. Panic would be unwise, but no one acquainted with the history of plague can regard the present situation with indifference.

DR. J. MAES contributes to the February number of *Man* an account of certain remarkable fetish images of the Wazimba tribe, which have recently been acquired by the Congo Museum at Terveuren. Those illustrated are rude male and female figures, one of which guards children, a second watches young girls and presides over accouchements, a third guards the house, and a fourth protects people from nightmare. The treatment consists in making the patient, to the accompaniment of magical formulæ, drink an infusion of manioc leaves, which are first laid on the head of the fetish.

IN *Man* for February Mr. M. W. H. Beach describes, largely from hearsay, the strange Punan tribe in Borneo, a people well deserving further study. They are said to wear bark clothing, to have no houses or property, and to wander about the forest and sleep in trees. Intercourse with them is carried on by the methods of silent barter. They have the curious habit of leaping three or four yards at a time instead of walking, and their speed is marvellous. They kill game with the *sumpitan*, or blow-pipe, not by the usual method of blowing into the mouth, but by striking the end which contains the dart with the curved palms of their hands.

THE Journal of the Royal Society of Arts for February 10 contains a report of a lecture, by Capt. A. J. N. Tre-

mearne, on the Kagoro, a naked, head-hunting West African tribe occupying a mountain ridge running from the Bauchi into the Nassarawa province of northern Nigeria. They are notorious head-hunters, and there is a curious analogy between the objects and methods of the practice among them and the Nagas of Assam. Among both races it is a mark of social evolution, a young man showing his fitness for marriage by producing a head. Further than this, it appears, as in the case of the Meriah sacrifice of the Khonds or Kandhs, to be a means of promoting the fertility of the soil, a fowl in Nigeria being now the surrogate of the human victim which was not long since sacrificed by the Indian tribes.

PARTS v. and vi. of the Treasury of Human Inheritance (London: Dulau and Co., Ltd., 1911), issued by the Galton Laboratory for National Eugenics, consists of a monograph on the subject of hæmophilia, by Drs. W. Bullock and Paul Fildes. The authors are to be congratulated on the very thorough manner in which they have performed a task the magnitude of which can be realised when it is stated that the literature list contains full references to and descriptions of 949 separate works. Two hundred and thirty-five pedigrees are diagrammatically represented, and such available clinical notes are provided for each person said to have suffered from the disease as would enable a medical man to form an opinion as to the validity of the diagnosis. Many of these pedigrees deal with a very large number of individuals; thus that of the Tenua families includes eight generations and about 400 persons. Enough has been said to show that a rich mine of material has been opened up, and we hope that it will be worked by the experts in heredity. If they desire fuller information on any point or doubt the accuracy of what is contained in this volume, the excellent bibliography will make reference to the original sources easy for them.

IN an article on natural hair-balls in *The Field* of February 25, Mr. Lydekker records the fact—apparently not referred to in any book on reptiles or general natural history—that the stomachs of South American alligators (caimans) not infrequently contain large balls of hairs, derived, doubtless, from mammals which formed their prey. The evidence rests on the testimony of Mr. J. S. da Costa, who brought home a specimen—now in the Museum of the Royal College of Surgeons—and who states that, in the belief of the natives, such accumulations eventually lead to the death of the reptiles. A hair-ball composed mainly of tenrec-hair, brought to England from Madagascar by Mr. A. Dobrée, may indicate that Old World crocodiles are afflicted in the same manner, although this cannot at present be regarded as certain.

BREEDERS should be much interested in an article, by Mr. R. Bunsow, in the second number of the new serial *The Mendel Journal*, on the inheritance of coat-colour in thoroughbred horses. Taking up the subject from the established fact that bays (including browns) may be either pure as regards the power of transmitting their colour, or impure, when they may give rise to chestnuts, the author states that bays, as being capable of producing offspring of a colour different from their own, are a dominant type (D), while chestnuts, which lack this capacity, are recessive (R). Chestnut horses, as having but one kind of sexual cells, may accordingly all be symbolised as RR, whereas bays may be classed either as DD or DR, according to whether they are pure or whether they contain an admixture of chestnut cells. Now if a DD stallion be mated with an RR mare, all the foals will be DR bays. On the other hand, the foals of an RR mare by a DR stallion will, in the long run, consist of bays and chestnuts in nearly equal numbers. When chestnuts are bred together, their offspring should be all chestnuts (RR), but if chestnuts be crossed with bays, the foals may be either all bays or half chestnuts (RR) and half bays (DR), the former case, as mentioned above, being due to the fact that the parent bays were DD, and the latter to their being DR. Certain exceptions to these conditions occurring in the Stud-book are shown to be due to incorrect registration of colour, and it is probable that the same is the case with the rest. As regards greys, it is asserted that one of the parents must be of this colour.

A SUMMARY, by Mr. A. B. E. Hillas, of reports received relative to the movements of eel-fry during the year ending September 30, 1909, has been received from the Irish Department of Agriculture and Fisheries (Fisheries, Ireland, Sci. Invest., 1910, vi.). This summary, which is a continuation of that of the previous year, presents the substance of replies given to four questions, widely circulated among those likely to be able to give information of the movements of eel-fry in the various river systems. The information at present available is not sufficient to permit the author to state with certainty whether the successive immigrations of fry form parts of one continuous annual series or are divisible into two or more seasonal runs; the facts reported from Wexford seem to support the latter view, whereas in the Coleraine district there was a run from March to June, which was practically continuous from April 21.

A LIST of wild flowers recorded from Barmouth and the neighbourhood is published by Mr. James Kynoch, Brighton. The most interesting part is the list of plants, including cryptogams as well as phanerogams, compiled by the Rev. T. Salwey, and published in 1863, in which localities in the county of Merioneth outside the Barmouth district are given.

PROCEEDING from the appearance of a variant *Œnothera rubricalyx*, distinguished from its progenitor *Œnothera rubrinervis* by increased red coloration in parts of the plant, Dr. R. R. Gates communicates to the *American Naturalist* (April, 1910) an article in which he discusses the bearing of what is regarded as an instance of quantitative colour inheritance, concluding that in many cases the difference between Mendelian hybrids must be simply quantitative, involving a difference either in the amount of certain material substances or in the energy content of certain constituents.

CONTINUING his revisions of fungal species in the *Sitzungsberichte der Kaiserlichen Akademie der Wissenschaften*, Vienna (vol. cxix., part v.), Prof. F. von Höhnel discusses a number of Ascomycetes, and presents a scheme for classifying the Microthyriaceæ. To the same number Miss J. Menz contributes a paper on the morphology of the genus Allium, in which the taxonomic value of the leaf bundles is considered, and a relationship between the Allioideæ and Amaryllidoideæ is suggested, primarily owing to the development of mucilage canals and cells containing raphides.

A FIRST contribution to the flora of Siam, published in the *Kew Bulletin* (No. 1), is jointly provided by Dr. A. F. G. Kerr, who collected the plants and has written an introductory sketch of the vegetation on Doi Sootep, a mountain in northern Siam, and by Mr. W. G. Craib, who is responsible for the identifications. Different types of forest are associated with *Pentacme siamensis*, *Dipterocarpus tuberculatus*, species of Quercus and Castanopsis,

Pinus Khasya, and *Quercus Junghuhnii.* In several of the associations, epiphytes, chiefly orchids and ferns, are a characteristic feature; *Dischidia Rafflesiana, Agapetes Hosseana*, and *Rhododendron Veitchianum* are notable epiphytes. Mr. Craib's list, which is confined to the Polypetalæ, contains a number of species new to science, and a type of a new genus, Pittosporopsis, in the family Icacinaceæ. A very large preponderance of species in the family Leguminosæ is due partly to the number of genera and partly to the variety of species in the genera Desmodium, Crotalaria, Cassia, and Bauhinia.

IN the *Cairo Scientific Journal* for January, Mr. W. Cartwright has an article on the control of the cotton aphis, thus adding one more to the many useful communications relating to cotton cultivation which have appeared in that journal during the past four years, during which but little has been done officially to promote research in this important field.

IN a recent paper (*Bull. de l'Acad. Imp. de Sci. de St. Pétersbourg*, 1911, No. 2) Prince Galitzin discusses the records obtained at Pulkowa of the great earthquake of January 3–4. He finds that the epicentre was situated in lat. 43° 14′ N., long. 78° 24′ E., an estimate which agrees closely with that obtained from the records at Eskdalemuir of lat. 42° N., long. 77° E. Both points lie close to Lake Issyl-kul, and to the epicentral area of the great Vyernyi earthquake of June 9, 1887.

THE seismological bulletins of the observatory at Zikawei for November and December, 1910, consist of registers obtained from Omori and Weichert pendulums. The former weighs about 15 kilos., and the latter about 1200. In December the heavier of these instruments gave twenty-three records, whilst the lighter only gave eighteen. Three out of the twenty-three seem to be peculiar to Zikawei, whilst the remaining twenty were also recorded in Great Britain, and probably at most stations in the world.

A POPULAR article by a resident at Innsbruck, the capital of Tyrol, on the Föhn wind as it strikes an observer, appears in *Symons's Meteorological Magazine* for February. This blows at times with considerable force, sweeping northwards from the Brenner Valley as a warm, dry wind, raising clouds of dust in its track. If it is summer, the atmosphere becomes stiflingly hot, if winter, the keen, frosty air turns mild and close; and it sometimes exerts a depressing influence on the nervous system. From twenty-five years' observations supplied by Dr. H. v. Ficker, Innsbruck has an annual average of forty-three days of Föhn; it is most frequent in spring (seventeen days) and autumn (eleven days). It generally lasts one or two days; twice in the above period it lasted eight days. On vegetation it has its advantages, *e.g.* Innsbruck owes its crops of maize to it, and some floral types from the inter-Glacial period still survive in the Inn Valley. Its attacks are mild compared with those in certain Swiss valleys, where it sometimes uproots trees by its fury.

IN the Australian Monthly Weather Report for March, 1910, Mr. H. A. Hunt gives a very interesting account of a hurricane of exceptional severity that visited the Fiji group of islands on the 24th and 25th of that month. The storm was a remarkable one, and its track can be followed for some 2500 miles from Fiji to New Caledonia, Norfolk Island, and the North Island of New Zealand, where it arrived on the morning of the 30th. The harbour master at Suva states that its approach was quite unexpected; the heat was excessive, but the barometer gave scarcely any warning. At midnight it was falling; at 2h. a.m. it stood at 29·00 in., and the easterly wind was increasing, with heavy rain. At 3h. a.m. it was blowing with hurricane force, and sheets of iron were flying from all directions between E. and N.E.; at 4h. a.m. the barometer had fallen to 28·50 in., and then began to rise. At Levuka there was a calm of about ten minutes as the votex passed over the town, with a complete change of direction, but at Suva the wind simply backed from E. to N.N.E. as the barometer rose. The isobaric charts show that the storm followed the usual track, moving in a W.S.W. direction until caught in the easterly atmospheric drift of mid-latitudes, when it curved to the south-east.

IN the January number of the *American Journal of Science* appears a communication by Dr. L. A. Bauer on gravity determinations at sea, in which he discusses the results obtained by Dr. Hecker in 1901, 1904, and 1909, and indicates the direction in which efforts are being made to attain more satisfactory results during the cruise of *Carnegie*, starting from Cape Town about April, 1911. In spite of the most elaborate precautions which were taken in Hecker's trips, trouble was experienced with the boiling-point thermometers employed to determine the atmospheric pressure in order to compare it with the height of the mercurial column, which, under the same conditions, changes with variations of gravity. Experimental work with boiling-point thermometers was carried out on the *Carnegie* in 1909–10, and the results showed that it would be worth while to attempt gravity work on board of her. The methods and reductions hitherto employed are discussed, and the view is expressed that some error may attach to the results obtained by the boiling-point thermometers, and that in the method of reduction local gravity anomalies observed during a cruise partake of the nature of accidental errors. On the *Carnegie* it is proposed to make both shore and harbour observations, especially at places where pendulum observations have already been made; frequent zero determinations of the thermometers, and comparisons of the barometers with shore standards, wherever available, are to be employed to determine the various errors. The necessary refinement of the barometric work remains as the chief difficulty, and the hope is expressed that, in view of the great importance of the subject, a method superior to the present may be discovered whereby the boiling-point thermometer may be eliminated.

IN an original memoir in the January number of *Le Radium*, M. G. Sagnac, of Paris, shows that in order that the time occupied by two beams of light in describing in opposite directions the contour of an area of considerable magnitude may be the same, it is necessary and sufficient if the vector which defines the relative velocity of the æther with respect to the optical system is irrotational throughout the area enclosed by the contour. In order to test whether the æther in the immediate neighbourhood of the earth possesses this property, M. Sagnac divided a beam of light into two portions, which he sent in opposite directions round a circuit consisting of a horizontal length of about 30 metres, an equal vertical length, and a third sloping one joining the two former. The two beams after traversing the circuit interfere, and the bands are observed in a telescope allowing a determination of displacement of 1/1000 of the width of a band. The plane of the circuit being east and west, observations of the bands were taken at various hours of the day and night, but no displacements were observed equivalent to a change in the relative motion of æther and matter of 1 millimetre per second for an elevation of 1 metre. Any relative

motion that exists must, therefore, be practically irrotational.

THE Journal of the Franklin Institute for February contains a report on recent progress in the chemistry of the terpenes and camphors, by J. S. Hepburn. Similar reports dealing with the sugars and the proteins have appeared in the two preceding years. The present report is based upon Wallach's recently published volume on the "Terpenes and Camphor," and in the space of twenty-five pages gives an excellent summary, which is likely to be of service to those who are unable to make use of the German original.

MR. A. E. PORTER finds that a number of ferments, including pepsin, trypsin, and rennet, are rendered inactive by being kept in contact with artificial membranes, especially with collodion ones. Most ferments which have thus been inactivated have at the same time acquired inhibitive properties. The inactivation of ferments by membranes is not due to simple absorption, for there is no evidence of saturation of the membrane; on the contrary, its inactivating power appears to improve with repeated use. Although the inhibitive power of the inactivated ferments may be due in part to substances preformed in the solution, inhibition is still present after removal of these substances, suggesting that the ferment itself is changed by contact with a membrane into a substance having an inhibiting power on itself (*Quart. Journ. Experiment. Physiol.*, iii., No. 4, December, 1910, p. 375).

THE important discoveries of MM. Paul Sabatier and Senderens on the catalytic action of finely divided metals, notably nickel and copper, have recently been extended to a study of the catalytic action of various metallic oxides. In the current number of the *Comptes rendus* MM. Paul Sabatier and A. Mailhe give an account of a new synthetic method, based on the catalytic effect of titanium oxide, which would appear to possess many practical applications. They show that if a column of titanium dioxide is maintained at a temperature of 280°–300° C., and a mixture of the vapours of a primary alcohol and a fatty acid (other than formic acid) is led over it, the corresponding ester is formed. The same limit is here reached instantaneously as was found by Berthelot after prolonged contact. An excess of either constituent favours the limit of combination of the other. Following this method, the methyl, ethyl, propyl, butyl, isobutyl, and isoamyl esters of acetic, propionic, butyric, isobutyric, isovaleric, and caproic acids have been prepared. Esters of benzyl alcohol have also been readily obtained by this method. The inverse action—the direct hydrolysis of esters by water—is also easily effected, and the use of titanium dioxide reduces any secondary reactions to a negligible amount.

AN article on ferro-concrete beams with single reinforcement appears in *Engineering* for March 3, from the pen of Dr. W. C. Unwin. The object of the article is to put the equations of the ordinary theory into the most convenient form for calculation. The ordinary theory is known to be only roughly approximate, but the assumptions made are believed to be generally on the side of safety. The formulæ, however, are still in some cases very complicated, as given in books, due to the attempt to obtain formal exactness from a mathematical point of view. But the data used in solving problems are themselves only approximate; for instance, the selected value of the coefficient of elasticity of concrete, which itself varies with the stress, and the neglect of the tensile stress in the concrete. Hence it would appear that, for practical purposes, a sacrifice of mathematical exactness in the form of the equations is justifiable, if the errors are small within a practical range. In fact, some of the equations are only used in designing by making assumptions and proceeding by trial and error, or by the use of tables and curves based more or less on experience. Both rectangular and T sections are dealt with in the article, and examples are given of the use in practice of the simplified formulæ deduced.

A COPY has been received of the first number of the *Irish Review*, a monthly magazine of Irish literature, art, and science. Science is represented only by an article on economics by Mr. George W. Moore, in which he deals with the problem of rural life. The magazine is published in Dublin, and may be obtained in London from Messrs. Simpkin, Marshall, Hamilton, Kent and Co. The price is 6*d*. net.

THE annual report for 1910 of the Philosophical Institute of Canterbury, New Zealand, shows that the condition of the institute continues to be satisfactory both as regards the number of members and the active interest displayed in those branches of science which constitute its object. The special lines of research outlined in last year's report have been developed, and some have already given good results. These lines of inquiry are:—observations on the Arthur's Pass tunnel; a survey of the Canterbury lakes; and an examination of the Christchurch artesian system. This is quite apart from the original work which has been carried on by individual members of the institute. A subcommittee has also been considering the question of the more adequate protection of the native fauna. Ten meetings of the institute were held during the year, at which the average attendance was sixty-four. At these meetings twenty-seven papers embodying the results of original research were read. These are classified as follows:—botany, four; zoology, seven; geology, five; chemistry, six; physics, two; mathematics, one; miscellaneous, two.

OUR ASTRONOMICAL COLUMN.

THE BRILLIANT METEOR OF FEBRUARY 19.—Mr. W. F. Denning writes:—"A very good observation of this object comes from Mr. Felix de Roy, of Antwerp, who describes the apparent path as from 27°+34° to 11°+60°, and onwards to the north-east. He gives the duration as twelve seconds, but this only relates to a portion of the flight. To him the meteor disappeared in a cloud.

"At Putney the object was seen by Mr. F. E. Baxandall, who gives the duration as fifteen seconds, but I do not know whether the newspaper account of his observations includes the course of the meteor. The radiant point appears to have been at 46°−15° in Eridanus, and the heights 70 to 49 miles along a path 590 miles long, and probably this does not include the whole extent of the visible luminous trajectory. Its motion seems to have passed from over the English Channel between Brest and Plymouth to Oldenburg, in Hanover. From Stowmarket the meteor was seen to rise from the south-west horizon, and at Antwerp it was low in the north-east when it disappeared. The meteor may therefore have sailed along in a nearly horizontal flight much further, but it was rising, not falling, to the earth when last seen.

"This meteor, though of such an extended course, is not beyond precedent, for according to the computations of the late Prof. Herschel the fireball of August 18, 1783, had a path of 1000 to 1200 miles; that of September 5, 1868, was watched along 880 miles; while that of July 20, 1860, was traced more than 1000 miles. It will be important to secure observations of the meteor of February 19 from Cornwall or the north-west coast of France, and from Holland and Hanover or that region."

HALLEY'S COMET.—Dr. Ebell publishes a bi-daily ephemeris for Halley's comet, extending to April 30, in No. 4476 of the *Astronomische Nachrichten*. Although the comet is not likely to be observed with ordinary instru-

ments, it is interesting to note that its present position is 10h. 30·2m., $-13°$ 48·2′, roughly about one-third of the distance from υ towards λ Hydræ; it is travelling north and west, towards Sextans, and its distance from the earth is about 330 million miles. Prof. Barnard's observation, of January 8, gives a correction to Dr. Ebell's ephemeris of $+12$s., $-0·5′$, and the ephemeris shows that by April 30 the comet should be about one magnitude fainter than when Prof. Barnard saw it.

The Angular Speed of Rotation of a Long-enduring Prominence.—From the study of the Kodaikánal spectroheliograms of a prominence which endured, in more or less the same form, for eighty-two days, Mr. Evershed arrives at some important conclusions, which he publishes in No. 1, vol. xxxiii., of the *Astrophysical Journal*. When first photographed, the prominence was on the western limb, was 55″ high, and covered from $+2°$ to $-14°$ in latitude. Its seventh, and last, "limb" appearance was on April 28, when it was 80″ high, and extended over latitudes $-7°$ to $-23°$; on each occasion, after the first, it was seen for three successive days on the limb. Not only was this object photographed on the limb, it is also seen as an absorption marking on a number of "disc" photographs taken, and is shown as such on the four magnificent photographs reproduced.

Measures of the photographs show that the dark mass of calcium (and hydrogen) vapour near the equator had, during February, a speed 5 per cent. greater than the general surface of the photosphere, and, during the March apparition, a speed 11 per cent. greater. They also indicate that the two apparitions really represent two distinct masses of gas emanating from a common origin in solar longitude 75°. The general aspect and behaviour of the prominence suggest that it was continuously renewed by glowing gas emanating from numerous photospheric orifices.

The enormous activity attending such phenomena is indicated by the fact that, on March 25, the prominence extended over at least 36° of latitude, or was 250,000 miles long, yet twenty-four hours later the whole object had completely vanished.

Radial-velocity measures made when the prominence was on the limb, on March 17 and 18, showed that the prominence, at a considerable height, was moving at a speed 34 per cent. greater than the normal chromosphere, and they suggest that the acceleration of velocity with height, discovered by Adams, may be continued beyond the limits of the chromosphere. The measures were made, with a radial slit set across the limb at the equator, on the Hα line, and the difference measured was that between the absorption line, representing the normal chromospheric line, and the bright prominence line.

Conjunctions of Major Planets and Stars in 1911.—According to Prof. Banachiewicz, in No. 4465 of the *Astronomische Nachrichten*, there will be three near conjunctions with Mars and one occultation by Jupiter this year.

On May 3, at 11h. (G.M.T.), Mars will be in conjunction with and 18″ S. of B.D. $-10°$ 5892, a star of magnitude 7·5; on May 10, at 12·6h., the planet will pass 0·8′ S. of the sixth-magnitude, fundamental star h Aquarii, and on August 9, at 11·7h., it will pass within 15·5″ of the star AG. Lpz. I. 898 (mag. 8·5); it is possible that the unknown proper motion of the star may make this an occultation.

The star B.D. $-12°$ 4042 (mag. 6·5) will be occulted by Jupiter on August 13 at 0·2h. G.M.T., and the phenomenon will be observable in Australia and eastern Asia.

Astrophysics in the United States.—The *Revue générale des Sciences* for February 15 (No. 3) contains a very interesting illustrated article, by M. Bosler, in which the author summarises the recent progress of astrophysical methods in the United States. M. Bosler includes the methods employed at Harvard in the systematic study of the stars and their spectral classification, the radial-velocity and other researches at Mount Hamilton, the multifarious observations made at the Yerkes Observatory, and the great progress in methods, instruments, and knowledge which has taken place at Mount Wilson since the solar observatory was founded on its elevated site. The article is freely illustrated with photographs, and gives an excellent idea of the great advances made in our knowledge of the universe under the favourable financial and climatic conditions which obtain in the States.

Studies of Algol Variables.—The Journal of the College of Science, Imperial University of Tokio, for January 18, contains a paper, in English, by Mr. Naozo Ichinohe, in which the author discusses a large number of variable stars of the algol type. After giving a brief historical account, Mr. Ichinohe defines an algol variable, and then gives a list of ninety-three stars which conform to his definitions. He then discusses the periods, densities, distribution, magnitudes, spectra, &c., and, with a number of tables, makes up a useful epitome of our knowledge concerning this type of star.

The Spectroscopic Binary u Herculis.—In 1848, the star u Herculis was suspected by Schmidt to vary; but its light-changes were puzzling, and it was not until 1869 that he concluded it to be a variable, with a period of about forty days, which at minimum suffered rapid changes. Frost and Adams, in 1903, showed the star to be a spectroscopic binary.

In No. 9, vol. ii., of the Publications of the Allegheny observatory, Dr. Baker discusses the radial velocities of this star, determined from spectrograms taken with the Mellon spectrograph, and finds it to be an eclipsing variable of the β Lyræ type, with a period of 2·051 days, and a secondary minimum about a day later. The presence of this secondary minimum, and the presence of the fainter spectrum on the plates, afford a unique opportunity of ascertaining the relative densities of the two stars and other data bearing on the question of double-star evolution. Dr. Baker finds that the diameter of either star is nearly six times that of the sun; that the brighter star (visual mag. = 5·0) is 7·5 as massive, but only one twenty-seventh as dense as the sun, while the fainter star (mag. 6·0) is 2·9 times as massive and one-seventieth as dense; that the centre of gravity of the system lies well within the surface of the brighter star, its mean distance from the centre of each body being 2,900,000 and 7,300,000 km., respectively, and that the surface brightness of the massive star is 2·5 times that of the other, although the spectra are practically identical. If the parallax were accurately known, it would be possible to determine, for this case, whether helium stars, such as these two are, or solar stars, have the greater surface brightness; assuming the parallax to be 0·02″ or greater, it would appear that the surface brightness of the fainter star, at least, is less than that of our sun.

FORTHCOMING BOOKS OF SCIENCE.

Agriculture.

A. and C. Black.—Wheat-growing in Canada, the United States, and the Argentine, W. P. Rutter, illustrated. *T. Werner Laurie.*—The Training of the Farmer, Dr. L. H. Bailey. *John Murray.*—Imperial Institute Series of Handbooks to the Commercial Resources of the Tropics, with special reference to British West Africa, issued under the authority of the Secretary of State for the Colonies, and edited by Dr. W. R. Dunstan, F.R.S.:—The Agricultural and Forest Products of British West Africa, G. C. Dudgeon, illustrated. *Swan Sonnenschein and Co., Ltd.*—Prosperous Agriculture: or Food Land the Raw Material, F. W. Wateridge, illustrated.

Anthropology.

Macmillan and Co., Ltd.—The Golden Bough: a Study in Magic and Religion, Dr. J. G. Frazer, third edition, in 6 parts, Part i., The Magic Art and the Evolution of Kings, 2 vols.; The Baganda, a General Survey of their Country, Life, and Customs, Rev. J. Roscoe, illustrated; The Nāga Tribes of Manipur, T. C. Hodson, illustrated. *John Murray.*—The Castes and Tribes of Eastern India, Sir H. Risley, K.C.I.E., C.S.I., illustrated. *The Oxford University Press.*—The Suk: their Language and Folklore, M. W. H. Beech, with introduction by Sir C. Eliot. *Swan Sonnenschein and Co., Ltd.*—Bushman Folk Lore, Miss L. C. Lloyd, with a preface by Dr. G. McCall Theal, illustrated.

Biology.

Edward Arnold.—Practical Photo-micrography, J. E. Barnard, illustrated. *Baillière, Tindall and Cox.*—Micro-organisms, M. Herzog. *A. and C. Black.*—The Open Book of Nature, a Book of Nature-study for Young People, Rev. C. A. Hall, illustrated; The Life and Love of the Insect, J. H. Fabre, translated by A. Teixeira de Mattos, illustrated. *W. Blackwood and Sons.*—The Elements of British Forestry: a Handbook for Forest Apprentices, J. Nisbet. *The Cambridge University Press.*—An English Flora, Dr. C. E. Moss, assisted by specialists, 10 vols. probably, illustrated. *Cassell and Co., Ltd.*—The Nature-lover's Handbook; Breeding and the Mendelian Discovery, A. D. Darbishire, illustrated. *J. M. Dent and Sons, Ltd.*—Physiology Primer, Prof. C. S. Sherrington, F.R.S.; Zoology Primer, Prof. W. A. Herdman, F.R.S. *Duckworth and Co.*—Cacao: its Culture and Preparation, J. H. Hart. *Gurney and Jackson.*—A History of British Mammals, G. E. H. Barrett-Hamilton, continuation in parts, illustrated; Rhopalocera Exotica, being Illustrations of New, Rare, or Unfigured Species of Butterflies, H. Grose-Smith and W. F. Kirby, 3 vols., illustrated, reduced in price. *Henry Holt and Co. (New York).*—The Animals and Man, Prof. V. L. Kellogg, illustrated; Plant Life and Evolution, Prof. D. H. Campbell; a revised edition of Hertwig's Manual of Zoology, Prof. J. S. Kingsley; A Key to High School Botany, Prof. Atkinson. *T. C. and E. C. Jack.*—The British Bird Book, edited by F. B. Kirkman, illustrated, further sections; Present-day Gardening, edited by R. H. Pearson, illustrated; Rhododendrons and Azaleas, W. Watson; Carnations and Pinks, T. H. Cook, J. Douglas, and J. F. M'Leod; Roses, H. E. Molyneaux. *A. Melrose.*—The Biology of the Seasons, Prof. J. A. Thomson, illustrated. *The Methodist Publishing House.*—Butterflies, and How to Identify Them, S. N. Sedgwick. *Methuen and Co., Ltd.*—Studies of Trees and Flowers, M. Wrigley, illustrated; The Freshwater Fishes of the British Isles, C. T. Regan, illustrated; The Life of Crustacea, Dr. W. T. Calman, illustrated; Our Insect Friends and Foes, F. M. Duncan, illustrated; The Young Ornithologist: a Guide to the Haunts, Homes, and Habits of British Birds, W. P. Westell, illustrated; Preliminary Hygiene, W. Narramore, illustrated; Elementary Lessons on Plant Life, Miss D. G. Scott, illustrated. *Mills and Boon, Ltd.*—The Bee-keeper's Companion, S. S. Abbott, illustrated. *Milner and Co.*—Prehistoric Man, J. McCabe. *John Murray.*—Ornamental Bulbous and Tuberous Plants for the Open Air, Greenhouse, and Hothouse, with details as to Descriptions, Culture, and Propagation, J. Weathers, illustrated; The Genus Rosa, E. Willmott, drawings by A. Parsons, in parts, continued; Criminal Man—According to Lombroso, G. Lombroso Ferrero, and The Cell and Cellular Reproduction of Living Beings, Dr. Marcus Hartog (Progressive Science Series). *The Oxford University Press.*—Forest Terminology, J. Gerschel and W. R. Fisher, a new edition of the work published in France, and now printed in French, German, and English. *Kegan Paul and Co., Ltd.*—A History of Birds, Dr. H. O. Forbes. *Sir I. Pitman and Sons, Ltd.*—British Ferns: a Pocket Help for the Student and Collector, comprising all the Native Species and showing Where Found, F. G. Heath, illustrated. *G. Putnam's Sons.*—Neglected Factors in Evolution, H. M. Bernard. *Lovell Reeve and Co., Ltd.*—The Coleoptera of the British Islands, Rev. W. W. Fowler and H. Donisthorpe, supplementary volume; British Diptera, P. H. Grimshaw, in parts; The Flora of Tropical Africa, Sir W. T. Thiselton-Dyer, K.C.M.G., F.R.S. (continuation); Lepidoptera Indica, Col. S. Swinhoe (continuation). *Alston Rivers, Ltd.*—British Plants: their Biology and Ecology, J. F. Bevis, illustrated. *G. Routledge and Sons, Ltd.*—Alpine Plants of Europe, with Cultural Hints, H. S. Thompson, illustrated. *Smith, Elder and Co.*—Thoughts on Trout Fishing, H. Russell; Grouse Disease Enquiry. Under the direction of the Committee on Grouse Disease the general questions have been treated by A. S. Leslie, Dr. E. A. Wilson, and the scientific by Dr. A. E. Shipley, F.R.S.; subscription edition, in 2 vols., illustrated. *Swan Sonnenschein and Co., Ltd.*—Elementary Text-book of Practical Botany, for the Botanical Laboratory and Private Student, Prof. E. Strasburger, edited by Prof. W. Hillhouse, illustrated, new edition; Plant Life: a Manual of Botany for Schools, Prof. E. Warming, translated by E. Rehling and E. M. Thomas, illustrated. *John Wiley and Sons (New York).*—Forest Physiography, I. Bowman; Principles of Handling Woodlands, H. S. Graves. *Witherby and Co.*—Photography for Bird-lovers, B. Beetham, illustrated; The Birds of Australia, G. M. Mathews, illustrated, part ii.; A Fisherman's Summer in Canada, F. G. Aflalo.

Chemistry.

Edward Arnold.—The Chemistry and Testing of Cement, Dr. C. H. Desch. *A. and C. Black.*—Chemical Analysis, Qualitative and Quantitative, a Text-book for Technical Schools and Colleges, G. G. Gardiner, vol. i. *Gauthier-Villars (Paris).*—Notions fondamentales d'Analyse qualitative, Thomas and Gauthier; Analyses chimiques métallurgiques, J. Hognon. *Gurney and Jackson.*—Technical Methods of Chemical Analysis, edited by Dr. G. Lunge, translated, adapted, and edited by Dr. C. A. Keane, vol. ii. in two parts, and vol. iii.; The Manufacture of Sulphuric Acid and Alkali, with the Collateral Branches, a Theoretical and Practical Treatise, Dr. G. Lunge, vol. iii., Ammonia-soda, Processes of Alkali Making and the Chlorine Industry, new edition. *Henry Holt and Co. (New York).*—A revised edition of Noyes' Qualitative Analysis. *Longmans and Co.*—New Ideas on Inorganic Chemistry, Prof. A. Werner, translated, with the author's sanction, from the second German edition, by Dr. E. P. Hedley; The Chemistry of Synthetic Drugs and the Application of Chemistry to Pharmacology, P. May; Monographs on Biochemistry, edited by Drs. R. A. Plimmer and F. G. Hopkins:—Oxidation and Reduction, Dr. H. D. Dakin. *Sampson Low and Co., Ltd.*—Triumphs and Wonders of Modern Chemistry, Dr. G. Martin, illustrated. *Macmillan and Co., Ltd.*—Crystallography and Practical Crystal Measurement, Dr. A. E. H. Tutton, F.R.S., illustrated. *Methuen and Co., Ltd.*—Higher Mathematics for Chemical Students, J. R. Partington; Elementary Chemical Theory, J. M. Wadmore; A Practical Chemistry for Technical Institutes, Dr. A. E. Dunstan; Outlines of Physical Chemistry, Dr. G. Senter, new edition. *Kegan Paul and Co., Ltd.*—Crystals, Dr. A. E. H. Tutton, F.R.S., illustrated. *Swan Sonnenschein and Co., Ltd.*—Introduction to the Study of Organic Chemistry, J. Wade, illustrated; a re-issue of the revised edition. *John Wiley and Sons (New York).*—A Laboratory Manual of Inorganic Chemistry, E. C. Bingham and G. T. White; Introduction to Chemistry, Prof. W. Ostwald, translated by W. T. Hall and R. S. Williams, illustrated.

Engineering.

Constable and Co., Ltd.—The Encyclopædia of Municipal and Sanitary Engineering, edited by W. H. Maxwell and J. T. Brown, illustrated. *Gauthier-Villars (Paris).*—Recherche pratique et exploitation des mines d'or, G. Proust; Calcul et construction des Alternateurs mono- et polyphasés, H. Birven (traduit de l'allemand par P. Dufour); Formation et carrière de l'ingénieur-électricien, A. Blondel; Organisation des Usines, Ballewski (traduit de l'allemand par A. Mayer). *T. Werner Laurie.*—The Aëroplane—Past, Present, and Future, C. Graham White and H. Harper, illustrated. *Crosby Lockwood and Son.*—Engineer's Year Book for 1911, comprising Formulæ, Rules, Tables, Data, and Memoranda, forming a compendium of the Modern Practice of Civil, Mechanical, Electrical, Marine, Gas and Mine Engineering, H. R. Kempe, with a collaboration of eminent specialists, illustrated; Marine Steam Turbines, a Handbook for the use of Students, Engineers, and Naval Constructors, based on the work "Schiffsturbinen," Dr. G. Bauer and O. Lasche, translated from the German by M. G. S. Swallow, illustrated. *Longmans and Co.*—The Testing of Motive-power Engines, including Steam Engines and Turbines, Locomotives, Boilers, Condensers, Internal Combustion Engines, Gas Producers, Refrigerators, Air Compressors, Fans, Pumps, &c., R. Royds, illustrated. *E. and F. N. Spon, Ltd.*—The Theory and Practice of Model Aëroplaning,

V. E. Johnson, illustrated; The Corliss Engine, J. T. Henthorn and C. D. Thurber, illustrated; Handbook of Cost Data, H. P. Gillette, for contractors and engineers, illustrated; Well-boring for Water, Brine, and Oil, C. Isler, new edition, revised and enlarged; illustrated; Milling Machines and Milling Practice, a Practical Manual for the Use of Manufacturers, Engineering Students, and Practical Men, D. De Vries, illustrated. *Whittaker and Co.*—Elementary Aëronautics, or the Science and Practice of Aërial Machines, A. P. Thurston; The Practical Design of Reinforced Concrete Beams and Columns, W. N. Twelvetrees; Ventilation of Electrical Machinery, W. H. F. Murdoch; Design of Alternating Current Machinery, J. R. Barr. *John Wiley and Sons (New York).*—Railway Station Service, B. C. Burt; Rock Drilling, R. T. Dana and W. L. Saunders; Pumping Machinery, A. M. Greene, jun.; Notes on Plate Girder Design, C. W. Hudson. *Williams and Norgate.*—How to Build an Aëroplane, R. Petit, translated by T. O. B. Hubbard and J. H. Ledeboer, illustrated, new edition.

GEOGRAPHY AND TRAVEL.

A. and C. Black.—Geographical Pictures: Land Forms and how They are Made. In packets of six cards. (1) Structure of the Earth's Crust; (2) Elevation and Depression of the Land; (3) The Sculpture of the Surface; (4) Rivers, (6) The Ocean, (7) Volcanoes and Volcanic Activity (Sculpturing Agents); (9) Plateaus and Plains (Positive Land Forms); (12) Deserts, (13) Steppes, (14) Forests (Land Forms with Typical Vegetation); Geographical Diagrams and Land-forms Series, H. J. Snape, North America and Eurasia, South America, Africa, and Australasia. *Constable and Co., Ltd.*—Adventure, Sport and Travel on the Tibetan Steppes: an Account of the Travels of C. H. Mears and J. A. Brooke, W. N. Fergusson, illustrated. *Gauthier-Villars (Paris).*—Manuel de l'Explorateur, Blim and R. de L'Isle, new edition. *Henry Holt and Co. (New York).*—Influences of Geographical Environment, E. C. Semple. *Macmillan and Co., Ltd.*—Man and Beast in Eastern Ethiopia, J. Bland-Sutton, illustrated; Sport in the Nilgiris, F. W. F. Fletcher, illustrated. *The Oxford University Press.*—Historical Geography of the British Colonies, Sir C. P. Lucas, vol. v., part iii., Canada (Geographical), part iv., Newfoundland, both parts by J. D. Rogers; Australia: Physiographic and Economic Aspects, T. G. Taylor. *G. Philip and Son, Ltd.*—All the World in Picture and Story: a First Book of Geography, J. Riley; Practical Exercises in Geography: British Isles, with maps, C. R. Dudley; Elementary Practical Geography, E. Young; Series 2 of L'Estrange's Geographical Pictures: British Isles, Historical, Industries, Famous Scenery and Cities, with Notes, &c., P. H. L'Estrange. *Swan Sonnenschein and Co., Ltd.*—The Danube with Pen and Pencil, Capt. R. G. Baker, illustrated.

GEOLOGY.

Constable and Co., Ltd.—The Stone Age in North America, W. K. Moorhead, 2 vols., illustrated. *Dulau and Co., Ltd.*—The Zones of the Chalk in Hants, C. Griffiths and R. M. Brydone, with appendices by the authors of Bourgueticrinus and Echinocorys, and by Dr. F. L. Kitchin on a new species of Thecidea, illustrated. *Macmillan and Co., Ltd.*—Geology and Geography of Northern Nigeria, Dr. J. D. Falconer, illustrated. *Milner and Co.*—Geology: Chapters of Earth History, G. Hickling. *John Murray.*—Student's Elements of Geology, Sir Charles Lyell, revised by Prof. J. W. Judd, C.B., F.R.S., new edition, illustrated. *E. and F. N. Spon, Ltd.*—Tables for the Determination of Common Rocks, O. Bowles. *Whittaker and Co.*—Mineralogy: the Characters of Minerals, their Classification and Description, Dr. F. H. Hatch, new and enlarged edition.

MATHEMATICAL AND PHYSICAL SCIENCE.

A. and C. Black.—Practical Physics, a Text-book for Technical Schools and Colleges, A. McLean, vol. i.; Climatic Control, L. C. W. Bonacina, illustrated. *Cassell and Co., Ltd.*—Practical Electricity, the late Prof. Ayrton, F.R.S., and Prof. T. Mather, F.R.S.; Astronomy for All, B. H. Bürgel, translated by S. Bloch, illustrated. *John Murray.*—A School Calculus, A. M. and J. D. McNeile. *Gauthier-Villars (Paris).*—Les principes de l'Analyse, R. d'Adhemar; Essai de Géométrie analytique modulaire, G. Arnoux; Précis d'Optique, P. Drude, publié d'après l'ouvrage allemand, refondu et complété par Marcel Boll, 2 vols.; Traité d'Energétique, P. Duhem, 2 vols.; Cours d'Analyse mathématique, E. Goursat, tome ii., 2e édition; Œuvres, Ch. Hermite, tome iii.; Théorie des fonctions métasphériques, Prof. N. Nielsen; Œuvres, W. Ritz; Précis de Télégraphie sans fil, Zenneck, traduit de l'allemand par MM. Blanchin, Guérard et Picot; Leçons sur le prolongement analytique, Zoretti. *Harper and Brothers.*—The Birth of Worlds and Systems, Prof. Bickerton. *Longmans and Co.*—Tables of Physical and Chemical Constants and some Mathematical Functions, Dr. G. W. C. Kaye and Prof. T. H. Laby. *Macmillan and Co., Ltd.*—Elementary Dynamics, Prof. A. Gray, F.R.S.; A School Algebra, H. S. Hall, part ii.; A New Algebra, S. Barnard and J. M. Child, part v. *Methuen and Co., Ltd.*—Practical Physics: a Laboratory Course for Advanced Students, S. S. Richardson, illustrated. *John Murray.*—The Tides and Kindred Phenomena of the Solar System, Sir G. H. Darwin, K.C.B., F.R.S., illustrated. *Kegan Paul and Co., Ltd.*—Light and Photography, Dr. H. Vogel and A. E. Garrett, revised and brought up to date by A. E. Garrett, illustrated. *E. and F. N. Spon, Ltd.*—Simple Treatise on the Planimeter and Land Area Tables, W. Codd; Barlow's Tables of Squares, Cubes, Square Roots, Cube Roots, Reciprocals of all Integer Numbers up to 10,000. *John Wiley and Sons (New York).*—Descriptive Geometry, J. C. Tracy and H. B. North.

MEDICAL SCIENCE.

Edward Arnold.—A Pocket-book of Treatment, Dr. R. W. Leftwich. *Baillière, Tindall and Cox.*—Atlas of First Aid, B. Myers; Military Sanitation, E. B. Knox. *A. and C. Black.*—Text-book of Operative Surgery, Dr. Th. Kocher, third English edition, translated from the fifth German edition by H. J. Stiles, illustrated. *Cassell and Co., Ltd.*—A System of Surgery, edited by Dr. C. C. Choyce and Dr. J. M. Beattie, vol. i., dealing with General Surgery and Surgical Pathology, Surgical Bacteriology, Shock, X-Rays, Anæsthetics, Specific Infective Diseases, &c., illustrated. *J. and A. Churchill.*—A System of Treatment, by British Authors, in four volumes, edited by Drs. A. Latham and T. C. English, vols. i. and ii., General Medicine and Surgery, vol. iii., Special Subjects, vol. iv., Gynæcology and Obstetrics; A Text-book of Diseases of the Skin, Dr. J. H. Sequeira, illustrated; Materia Medica, Step by Step, A. W. Nunn; The Refraction of the Eye, G. Hartridge, new edition, illustrated. *Constable and Co., Ltd.*—The Economy of Food: a Popular Treatise on Nutrition, Food and Diet, by J. Alan Murray. *Henry Frowde and Hodder and Stoughton.*—"606" and other Recent Advances in the Treatment of Syphilis, Prof. Ehrlich and J. R. McDonagh. *Macmillan and Co., Ltd.*—A System of Medicine, by Many Writers, second edition, edited by Sir Clifford Allbutt, K.C.B., F.R.S., and Dr. H. D. Rolleston, vol. ix. (concluding the work), Diseases of the Skin; Deformities: a Treatise on Orthopædic Surgery, intended for Practitioners and Advanced Students, A. H. Tubby, new edition, 2 vols., illustrated; Disease in Bones and its Detection by the X-Rays, E. W. H. Shenton, illustrated; Diseases of the Ear, Drs. W. Milligan and W. Wingrave, illustrated; An Introduction to Therapeutic Inoculation, D. W. Carmalt-Jones; Text-book of Human Physiology, Dr. L. Luciani, translated by F. A. Welby, and edited by Dr. M. Camis, with a preface by Prof. J. N. Langley, F.R.S., illustrated, in 4 vols., vol. i., Circulation. *Methuen and Co., Ltd.*—Unsoundness of Mind, Dr. T. S. Clouston, illustrated; Methuen's Health Readers, vol. i., C. J. Thomas. *Milner and Co.*—Medical Science, Dr. S. Hillier. *John Murray.*—Yellow Fever and its Prevention: a Manual for Medical Students and Practitioners, Sir R. W. Boyce, F.R.S., illustrated. *G. Putnam's Sons.*—The History of Medicine, Philosophical and Critical: from its Origin to the Twentieth Century, D. A. Gorton, 2 vols., illustrated. *Reb-*

man, Ltd.—The Abdomen Proper, Dr. W. C. Morton, illustrated; The Treatment of Syphilis with Dioxy-diamido-arseno-benzol ("Ehrlich-Hata 606"), Dr. W. Wechselmann, with an introduction by Dr. P. Ehrlich, illustrated. *Wm. Rider and Son, Ltd.*—Abnormal Psychology, Dr. I. H. Coriat.

TECHNOLOGY.

Cassell and Co., Ltd.—Hardening and Tempering Steel, a Workshop Guide to the Heat Treatment of all Steels, including High-speed, edited by B. E. Jones, illustrated; Electric Primary Batteries, edited by B. E. Jones, illustrated; Electric Accumulators, edited by B. E. Jones, illustrated; Cyclopædia of Photography, edited by B. E. Jones, in parts, illustrated. *J. and A. Churchill.*—The Principles of Aëroplane Construction, with Calculations and Formulæ, R. Kennedy, illustrated. *Constable and Co., Ltd.*—The Static Transformer, H. M. Hobart, illustrated; Handbook of Testing, C. A. Smith, part i., Materials, part ii., Prime Movers; Applied Thermodynamics for Engineers, W. D. Ennis, illustrated; Electric Furnaces and their Industrial Applications, J. Wright, new edition, illustrated; Arc Lamps and Accessory Apparatus, J. H. Johnson; Motors, Secondary Batteries, &c., S. K. Broadfoot; Electrical Mining Installations, P. W. Freudemacher; Building in London, H. Cubitt; Gas Engines, Capt. H. Riall Sankey, W. J. Marshall, illustrated; Wood Pulp, Charles F. Cross, E. J. Bevan, and R. W. Sindall, illustrated. *Gauthier-Villars (Paris).*—Systèmes cinématiques, *Crosby Lockwood and Son.*—Three-phase Transmission, a Practical Treatise on the Economic Conditions governing the Transmission of Electric Energy by Underground and Overhead Conductors, W. Brew, illustrated; Aërial or Wire Rope-ways, their Construction and Management, A. J. Wallis-Tayler, illustrated; The Modern Motor Car and its Mechanism, a Practical Handbook on the Management and Maintenance of the Car, for the use of Owners and Drivers, W. G. Duncan, illustrated; Short Specifications of Materials, Labour, and Goods, for Works connected with Building, J. Cubitt; Crushing and Grinding Machinery Practice, a Handbook on the Machinery used in Crushing and Grinding Operations on all classes of materials, T. G. Marlow, illustrated; Drying Processes and Patents, T. G. Marlow, describing the various Drying Processes as applied to Sundry Materials, also a Classified Summary of the Patents connected with Drying Processes and Apparatus; A Handbook on the Gas Engine, a Practical Treatise on the Design, Construction, and Running of Internal Combustion Engines, H. Haeder, translated from the German, with the addition of numerous useful tables and other matter by W. M. Huskisson, illustrated; Sewerage Systems, their Design and Construction, a Practical Treatise upon the principles of the Design, Construction and Maintenance of Town Sewerage Systems, with examples of existing works, H. S. Watson, with Legal Notes by E. B. Herbert, illustrated; Reinforced Concrete Design Simplified, Diagrams, Tables, and other data for designing and checking accurately and speedily, J. C. Gammon, with an introduction by H. K. Dyson; Technical Terms, English-German, German-English: a Pocket Glossary, suitable for the Engineering, Manufacturing, and Mining Industries, J. G. Horner, in collaboration with A. Schlomann. *Longmans and Co.*—A Practical Guide to Iron and Steel Analysis, for Students and others, W. Macfarlane; The Principles of Electro-deposition: a Laboratory Guide to Electro-plating, S. Field, illustrated. *Methuen and Co., Ltd.*—Rubber, Dr. P. Schidrowitz, illustrated. *Scott, Greenwood and Son.*—Spirit Varnishes and Spirit Varnish Materials, J. G. McIntosh, being vol. iii. of The Manufacture of Varnishes, illustrated; Casein: its Preparation and Technical Utilisation, translated from the German of R. Scherer, new English edition, revised and enlarged, illustrated; Lubricating Oils, Fats and Greases, their Origin, Preparation, Properties, Uses, and Analysis, a Handbook for Oil Manufacturers, Refiners and Merchants, and the Oil and Fat Industry in General, G. H. Hurst, illustrated, new edition; Edible Fats and Oils, their Composition, Manufacture, and Analysis, W. H. Simmons and C. A. Mitchell; Chemical Manures, translated from the French of J. Fritsch, illustrated; Chemical Works, their Design, Erection, and Equipment, S. S. Dyson and S. S. Clarkson, illustrated; Foods and Drugs, E. J. Parry and C. H. Bennett, vol. i., Chemistry and Analysis of Foods and Drugs, vol. ii., Law Relating to Foods and Drugs; Yarn and Warp Sizing in all its Branches, C. Kretschmar, translated from the German by C. Salter, illustrated; Dressings and Finishings for Textile Fabrics and their Application, Description of all the Materials used in Dressing Textiles: their Special Properties, the Preparation of Dressings and their Employment in Finishing Linen, Cotton, Woollen, and Silk Fabrics, Fireproof and Waterproof Dressings, together with the principal Machinery Employed, F. Polleyn, translated from the third German edition by C. Salter, illustrated. *E. and F. N. Spon, Ltd.*—Workshop Receipts, vol. iv., Rainwater Separators to Wire Ropes, new edition, illustrated. *Whittaker and Co.*—Electric Wiring Diagrams, W. P. Maycock; Colour in Woven Design, Prof. R. Beaumont, new and revised edition. *John Wiley and Sons (New York).*—How to Enamel, being a Treatise on the Practical Enamelling of Jewellery with Hard Enamel, illustrated; Metallurgy, a Brief Outline of the Modern Processes for Extracting the More Important Metals, W. Borchers, translated by W. T. Hall and C. R. Hayward; High-efficiency Electrical Illuminants and Illumination, R. W. Hutchinson, jun., illustrated; The Analysis of Non-ferrous Alloys, W. B. Price and R. K. Meade.

MISCELLANEOUS.

A. and C. Black.—A new edition of The Grammar of Science, Prof. Karl Pearson, F.R.S. *Dulau and Co., Ltd.*—A Monograph on Albinism in Man, Prof. Karl Pearson, F.R.S., E. Nettleship, and C. H. Usher, parts ii. and iii., illustrated. *Macmillan and Co., Ltd.*—The Psychology of Education, Prof. J. Welton; Ancient Hunters and their Modern Representatives, Prof. W. J. Sollas, F.R.S., illustrated. *Methuen and Co., Ltd.*—Body and Mind: a History and Defence of Animism, W. McDougall, illustrated. *John Murray.*—The Excavation of Gezer, 1902–5 and 1907–9, Prof. R. A. S. Macalister, illustrated. *The Oxford University Press.*—Excavations in Nubia, 1909–10, Prof. J. Garstang, F. Ll. Griffith, and Prof. A. H. Sayce. *Kegan Paul and Co., Ltd.*—Practical Archæology, Prof. Garstang; The Modern Science of Language, H. C. Wyld. *Rebman, Ltd.*—The Mechanism of Life, being the only authorised translation of Prof. S. Leduc's "Théorie Physico-Chimique de la Vie et Générations Spontanées," by Dr. D. Butcher; The Individual and Society: or, Psychology and Sociology, Prof. J. M. Baldwin. *Swan Sonnenschein and Co., Ltd.*—Physiological Psychology, Prof. W. Wundt, a translation of the fifth and wholly rewritten German edition by Prof. E. B. Titchener, in 3 vols., vol. ii., illustrated; The Adolescent, J. W. Slaughter; Scientific Romances, the late C. H. Hinton, reissues of "The Persian King," "Casting out Self," "A Plane World."

CANADIAN MINERAL STATISTICS.[1]

THE report before us contains a number of short articles on various points of special interest to those engaged in mining operations in Canada, and should prove of decided value to them, though it must be admitted that in the majority of cases the interest is mainly local. A short note refers to accidents in Canadian mines caused by explosives, and shows that the high accident death-rate is due to the absence of protective legislation in Canada. The following is given as the death-rate per 1000 miners in various parts of Canada:—

	per 1000
British Columbia, Coal Mines, 1899–1908 ...	9·21
Nova Scotia, Coal Mines, 1899–1908	2·67
British Columbia, Metal Mines, 1908	5·93
Ontario, Copper and Nickel Mines, 1907 ...	2·19
Ontario, Silver and Iron Mines, 1907	7·36

These figures afford convincing evidence of the need of a complete mining code, properly administered, seeing that there is nothing in the mining conditions of Canada to which so formidable a death-rate can fairly be ascribed.

[1] Canada, Department of Mines. Summary Report of the Mines Branch for the Calendar Year ending December 31, 1909. Pp. 31. No. 26*a*. (Ottawa, 1910.) Price 10 cents.

A summary of the mineral production of Canada for 1909 is given, some of the more interesting items of which are as follows:—

Metallic.

Copper	... ...	54,061,106 lbs.
Gold	... ... about	£2,000,000 sterling
Pig iron from Canadian ore	...	149,444 tons
Iron ore exports ...	... ...	21,956 ,,
Lead	... ...	45,857,424 lbs.
Nickel	... ...	26,282,991 ,,
Cobalt	... ...	?
Silver	... ...	27,878,590 ounces
Zinc	... ...	?

(In addition, there were produced 607,718 tons of pig iron from imported [Newfoundland] ore.)

Non-metallic.

Coal	... ...	10,411,955 tons
Asbestos ...	... .	63,349 ,,
Asbestic and asbestic sand	...	23,951 ,,
Petroleum ...	... ...	420,755 barrels
Pyrites	... ...	57,038 tons

In addition to products of less importance, a number of structural materials and clay products are also included in the returns. These returns have been modelled upon the mineral statistics of the United States, and thus copy faithfully all the mistakes of the latter, the principle having apparently been to get hold of a system that shall show the largest possible money value, irrespective of the consideration whether this is a true or a fictitious one. Thus the ores, or, as they are called in the returns, the metallic minerals, are valued by the amount of metal they contain, on the assumption that the whole of this metal can be extracted, and that its extraction and manufacture cost nothing; to get the grand total of the value of the mineral products, the total value of the coal mined is added to that of the metals thus calculated, though, of course, the manufactured value of a metal is made up in part, and often in large part, of the value of the coal used in smelting it; hence any coal used for smelting is valued twice over, and the same is true of the coal used in burning bricks, tiles, lime, &c. The values assigned are therefore so misleading that it appears better not to quote them. It is also surely incorrect to class arsenic, chromite, ochres, and pyrites amongst the *non-metallic* minerals. Although there are thus serious grounds for finding fault with the principles adopted in compiling the returns of mineral statistics, the work is, as usual, done thoroughly well, and gives evidence that the organisation of the Canadian Department of Mines has been put upon a highly systematic basis. H. L.

SCIENTIFIC RESEARCH IN AUSTRALASIA.[1]

THE Transactions and Proceedings of the New Zealand Institute form a very remarkable series of volumes, the contents of which deserve to be better known and appreciated in the mother country than would appear to be the case. They contain, amongst other things, the results of nearly half a century of investigation by New Zealand naturalists of the unique fauna and flora of their country, and local geologists and ethnologists have also contributed a large share to the imposing edifice of fact and theory which is gradually being built up. A generation of teachers, which included in its ranks such men as F. W. Hutton and T. J. Parker, could hardly fail to stimulate research—if stimulation were needed in a country where everything cries out for investigation.

The remarkable organisation of the New Zealand Institute, with its constituent societies in all the important centres of population, and the no less remarkable facilities for university education at the four university colleges, have no doubt also contributed largely to the result. Opportunities for original work have been abundant, and good use has been made of them. Much, of course, remains to be done in the future, and it will be very many years before New Zealand biologists have to seek "fresh fields and pastures new." In the meantime, the hope may be expressed that the New Zealand University may soon be able to see its way to an increase in the number of its science professors, accompanied by that necessary division of labour which has long been urgently called for. The professors themselves would then have more liberty for research work, and this is a matter of vital importance.

We believe there has never yet been a professorship of either botany or zoology, pure and simple, in New Zealand, and the botanical teaching has generally been in the hands of professors who have themselves specialised mainly in zoology. This fact makes the results attained all the more remarkable. The New Zealand University has always wisely insisted upon a course of general biology as the necessary foundation for both zoology and botany, and the fatal divorce which has taken place between the two subjects in the old country has thus to a large extent been avoided. We should be sorry to see this admirable arrangement upset, but surely some means could be devised whereby existing chairs could be divided without sacrificing the general biological training.

The forty-second volume of the Transactions and Proceedings of the New Zealand Institute marks a distinct advance upon its predecessors in the character of the illustrations, which in previous volumes have often left much to be desired. More care will have to be taken, however, in supervising the printing of the coloured plates. In the copy before us the registration of plate xxxi. is nearly an eighth of an inch out, producing a grotesque dislocation. One of the most interesting papers in the volume is "A Comparative Study of the Anatomy of Six New Zealand Species of Lycopodium," by J. E. Holloway, a pupil of Prof. A. P. W. Thomas; and Miss B. D. Cross has a well-illustrated paper on some New Zealand halophytes, treated mainly from the œcological point of view, in which the influence of Dr. Cockayne's work is clearly recognisable. Mr. Aston's "Botanical Notes made on a Journey across the Tararuas" deserves special mention on account of the beauty of the photographic illustrations.

Another noteworthy paper is that by Dr. C. Coleridge Farr and Mr. D. C. H. Florance, "On the Radio-activity of the Artesian-water System of Christchurch, New Zealand, and the Evidence of its Effect on Fish-life." The water from all the wells tested was found to contain a considerable amount of radium emanation, and when it first emerges from the well it has a very disastrous effect upon young fish and developing eggs. Experiments made in the fish-hatchery of the Canterbury Acclimatisation Society showed that the number of eggs dying increased in direct proportion to the amount of radium emanation present in the water.

We have also received two volumes of collected papers from the science laboratories of the University of Melbourne, published during the years 1906–9. We learn from Prof. Osborne's preface to the first volume that in March, 1908, the Government of Victoria made a grant of 1000*l.* to the University for the payment of scholarships in scientific research, and that in the two following years this sum was doubled. The result has been a marked increase in the amount of research by post-graduate students in science subjects.

The volumes before us contain numerous papers emanating from the departments of anatomy, biology, botany, chemistry, engineering, geology, natural philosophy, and physiology. These have been collected from very various publications and bound up together, and though they have been sorted out into two categories according to size, the resulting volumes are necessarily somewhat clumsy and awkward to handle. Unfortunately, also, they do not contain nearly all the papers published by members of the scientific departments of the university during the period selected, but they should serve to impress the supporters of the university with the large amount of valuable research work which is being done. As the different papers do not appear in these volumes for the first time, but were all originally published elsewhere, it is perhaps undesirable to attempt to notice them individually in this place. They form a highly interesting record of what is being done in the way of scientific research in the Melbourne University, and show a great amount of activity on the part of both teaching staff and students. THE MANUFACTURE OF VARIETIES OF COMMON SALT.

GREAT interest has been aroused among salt manufacturers by the announcement of the discovery of a new process capable of producing every variety of commercial salt in one plant and with great economy of fuel. The inventor is Mr. James Hodgkinson, of the firm of James Hodgkinson, Ltd., Pendleton, Manchester, makers of mechanical stokers. It is said that the patent rights for America have been sold to an American syndicate for 1,000,000*l.*, and to the Canadian Pacific Railway Company for Canada.

Up to the present time, salt has been manufactured by a process scarcely different from that used during the Roman occupation, namely, boiling down the brine in shallow open pans heated by coal fires. It is true that in 1839 Reynolds introduced the use of closed pans, in which the steam was passed from the first pan to the others, and a considerable economy in fuel effected, one ton of coal yielding four tons of salt, as against two tons in the case of open pans, which, however, still continued in use.

The chief features in the Hodgkinson process are the introduction of mechanical stokers for the fires, and the working of a plant consisting of seven pans, three closed and four open, heated by one fire. The quality and size of the salt crystals largely depend on the temperature, which can be so regulated in the new process as to produce every kind required.

The first pan is covered, and produces, by crystallisation alone, a table salt so fine that no grinding is required. From this pan proceed waste gases, which pass underneath and heat all the remaining pans, while the steam passes over to the succeeding pans and assists the precipitation of the salt. The second and third pans are also covered, and produce a slightly coarser variety, known as "dairy" salt. In the succeeding pans, all of which are open, the gases are at a lower temperature, and coarser salt in larger crystals is obtained. This is known as "fishery" salt, and is used in fish-curing. It should be added that there is an automatic flow of brine into the pans, and an automatic discharge of the salt produced.

The process, first successfully tried at Northwich, then extended to Port Sunlight and St. Helens, has resulted in such complete consumption of smoke that several large chimneys have been dispensed with. The success of the process must be assured if the hopes of the inventor are realised in practice. He claims that four or five times as much salt can be produced in a given time as compared with the old process, and that three tons of coal will be saved out of every four.

ARCHÆOLOGICAL RESEARCH IN ARKANSAS.[1]

MR. CLARENCE B. MOORE has issued another of his valuable memoirs on the prehistoric pottery of the United States. His last season's field work was on the St. Francis, Little, White, and Black rivers in Arkansas. Like all his other memoirs, this one is illustrated with maps and very numerous beautiful illustrations, many in colours, and all of large size, so that every detail is visible. Mr. Moore is still in the collecting stage of his work; generalisations we may expect at a future time. The principal sites along the St. Francis, although, as a rule, having mounds in connection with them, are in reality great dwelling-sites which have increased in height gradually through long periods of occupancy, and the aborigines, burying where they lived, have formed in course of time great cemeteries, all of which he believes to be pre-Columbian, since no object was found in any way indicating intercourse with Europeans excepting a bone comb, which, "though the shape is undoubtedly copied from a European model, the decoration points to Indian workmanship"; he asserts it is prehistoric.

The St. Francis valley has yielded more examples of its ware than has any equal area in the United States, and has been largely exploited by irresponsible collectors. The earthenware is shell-tempered. Quantity rather than quality seems to have been the aim of its makers, for the ware is often insufficiently fired, and the vessels are frequently thick and lop-sided. A high polish is almost absent. A very large proportion of the vessels are undecorated or with trivial decoration. Incised decoration is scarcely ever seen, the inferior surface of most of the ware being unsuited to incised decoration of excellent quality, even had it been attempted. Practically none of the vessels obtained by him are of types new to the pottery of the Middle Mississippi valley. The types of pottery have been well described by Prof. W. H. Holmes in his "Aboriginal Pottery of the Eastern United States" (20th Ann. Rep. Bur. Am. Eth). The most noteworthy find was a ceremonial "spear-head" of sheet-copper. Several vessels in the form of heads with fairly well-modelled faces were obtained, and some in the form of human figures. One burial of a very young infant had near by it a small bowl in which, upright, was a little effigy bottle.

Unlike the St. Francis river sites, which are on high ground, the sites on the White river and its upper reaches, the Black river, are on low, overflow ground, where archæological research is not likely to be rewarded; indeed, with a few trifling exceptions, no aboriginal objects had previously been obtained from this district. With one exception, no site of interest was found along the White river, and but three vessels of earthenware were encountered along the stream. Along the Black river, while some vessels were found, not one was of a character to warrant its transportation home. Although burials were fairly numerous, they were almost invariably unaccompanied by artifacts, a remarkable fact considering the custom of lavishing deposits upon the dead as practised by aborigines of neighbouring regions. The best find was a narrow, well-made ceremonial axe-head of green quartzite, 212 mm. in length.

A. C. HADDON.

[1] Journal of the Academy of Natural Sciences of Philadelphia. 2nd series, vol. xiv., part 2: "Antiquities of the St. Francis, White, and Black Rivers, Arkansas," by C. B. Moore, pp. 255-364 (Philadelphia, 1910).

THE COEFFICIENT OF SKIN FRICTION IN AIR AT MODERATELY HIGH VELOCITIES.

THE object of this study is to find a coefficient of turbulent friction readily applicable to the design of aërodynamic appliances such as aëroplanes and windmills.

It is assumed throughout that:—

(1) The surfaces on which the friction occurs are of reasonably smooth finish, and present no marked head resistance due to irregularities of surface.

(2) The velocities of the air relative to the surface are well above the critical values at which pure viscous shearing resistance is superseded by the generation of momentum in the contacting film or fluid, so that the skin resistance varies as the square of the velocity.

(3) The length of the surface in the direction of motion bears so small a relation to the dimensions perpendicular thereto that the diminution of the coefficient with the length is inappreciable.

The study is divided into two parts:—

(*a*) An analysis of the various methods of determining the skin-friction coefficient already known, with a tabular record of the numerical results already attained or thereby deducible, leading up to the most probable value of the said coefficient.

[(*b*) An experimental study made with the purpose of confirming the accuracy or otherwise of the said probable value. This is now in progress, the apparatus (an epicyclic differential dynamometer) being made. As this will not be ready for some considerable time, it may be useful to publish the comparative analysis beforehand.]

Symbols Employed.

British engineer's units—Pounds, feet, seconds. Force in lbs. wt.

f. Coefficient of skin friction.

C = about 0·7, being the coefficient of normal pressure on unit square surface, with unit velocity, and unit mass of air.

ρ. Mass of unit volume of air at normal temperature. About 0·08 pound per cubic foot.

A_1. Area subject to skin friction.

A_2. Area of mid-section or normal surface of a dirigible.

k. Ratio of skin friction on a dirigible to normal resistance on an area equal to the cross-section.

c. Coefficient of oblique air pressure (Lanchester). The value of this depends on the aspect ratio of the surface. From Duchemin's rule for square surfaces it is 2; Eiffel gives a value of 3; Lanchester gives hypothetical values between 2 and 3.

ξ. Ratio of skin friction on a double surface to the normal resistance of the plane of the same single-surface area.

β. Angle of incidence (Radians).

V. Relative velocity of air to surface.

l. Length of surface in the direction of flow.

A.

I.—*Frictional Resistance deduced from the Head, or Total Resistance of Dirigible Balloons.*

The resistance of a well-shaped dirigible is, like that of a ship, almost entirely due to skin friction. The aërodynamic resistance of cars, rigging, &c., is almost negligible in ratio to the skin friction, certainly not exceeding 30 per cent. thereof.

If, then, the area of the skin is A_1, and that of the maximum cross-section is A_2, and k is the ratio of the skin friction to the aërodynamic resistance of a normal surface with the same shape as the mid-section, this definition of k may be written:—

$$\frac{fA_1}{C\rho A_2}=k \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (1)$$

The coefficient k has been measured for several dirigibles, and forms the basis of this computation.

Name	Length	Diameter	A_1	A_2	k	f
Renard and Krebs	50·42 m.	8·4 m.	1330 sq.m.	55·4	0·4	0·000033
			(Espitallier, Genie Civil, 1902)			
Zeppelin III. ..	128	11 66	48000	100	0·45	0·000025
			(Moedebeck's Pocket Book)			
Lebaudy	53	10·3	2000	80	0·31	0·000030
				(Ditto.)		
Spherical Conoid.	6D	D	$6\pi D^2$	$\frac{1}{4}\pi D^2$	0·16	0·000014
			(Molesworth's Pocket Book[1])			
	Total ...					0·000102
	Mean value ...					0·000025
	Deduct 30 per cent. for other resistance ...					0·000008
						0·00001

The value 0·000025, seeing that it certainly includes some aërodynamic resistance due to imperfect form of envelope and the resistance of car and rigging, should be regarded as the absolute maximum.

II.—*Frictional Resistance deduced from the Efficiency of a Plane Aërofoil.*

According to Turnbull (*Physical Review*, March, 1907), the lift-to-drift ratio is a maximum for planes of an aspect ratio of two, when the angle of incidence is $3\frac{1}{2}$ degrees, and it has then a value of 5·1 ($3\frac{1}{2}$ degrees = 0·06 radian).

Employing Lanchester's notation, this ratio (also called by Turnbull the "efficiency")

$$=\frac{Cc\rho AV^2\beta}{\xi C\rho AV^2+Cc\rho AV^2\beta^2}$$

$$=\frac{c\beta}{\xi+c\beta^2}$$

c, according to Lanchester (compare Dines, Eiffel, and Rateau), is about 2·5, so that $\xi=0{\cdot}020$ for the double surface and $f=\xi C\rho=0{\cdot}000032$ for the double surface, or for the single surface 0·000015.

III.—*Frictional Resistance in Air deduced by Comparison with that of Water.*

The investigations of Froude have led to a fairly accurate knowledge of the frictional resistance of water, and it has been thought by many that a simple ratio exists between this and that of air in similar circumstances.

Froude's coefficients are between 0·003 and 0·005, the total resistance varying with a power of the velocity from 1·83 to 2·0 when there is considerable turbulence. It is probable that the lower density of air renders it more easily subject to turbulent conditions, so that there can be little doubt as to the approximate truth of the velocity squared hypothesis.

(*a*) Assuming that the friction is purely dependent on the density, since the density of water is about 800 times that of air, f may be $=0{\cdot}004/800=0{\cdot}0000052$.

(*b*) Assuming that the friction varies as the density, and also as the square root of the kinematic viscosities, an assumption consonant with hydrodynamic theory,

$$f=\text{sq. root of } 12\times0{\cdot}004/800=0{\cdot}000017.$$

IV.—*Zahm's Investigations.*

Prof. Zahm, by experimenting in a wind tunnel on boards, obtained a formula as follows:—

$$f=0{\cdot}000008\ l^{-0{\cdot}07}\ V^{18{\cdot}5}$$

for smooth surfaces and no vibration, increasing up to $f=0{\cdot}00001$ (total resistance varies with V^2) for turbulent conditions and buckram-covered surfaces.

V.—*Lanchester's Investigations.*

Index of velocity variation = 2.

Mr. F. W. Lanchester, experimenting with gliding models, and also with an aërodynamic balance (similar to that designed by Ritter von Loessl), obtained various results.

HERBERT CHATLEY.

[1] This result is apparently after Pole's figures, but the resistance seems to have been under-estimated.

BIOLOGY OF THE EEL-FISHES, ESPECIALLY OF THE CONGER.

DURING the Atlantic and Mediterranean cruises of the Danish research steamer *Thor*, in the winter of 1908–9 and summer of 1910, a very large material has been collected of the larvæ of the eel-fishes (Leptocephali). These belong to at least twelve different forms, and several of them can be referred to their parent species.

The material is specially rich in a few of the forms, and this permits of important conclusions being drawn with regard to the biology of these species. At the same time, it has yielded valuable information regarding the occurrence of the very youngest stages (pre-Leptocephali)—information which has long been desired and sought after; and, lastly, it has aided us in the determination of the age of the older Leptocephali, a question which the hitherto available information has been quite unable to settle.

The species of eel which is of the greatest practical interest in Great Britain is the Conger, and of this we have now a very large and complete material. Several hundred specimens have been taken—in all stages, from a length of only 9 mm. up to ca. 160 mm.

The larvæ are not difficult to determine, in part from the number of myomeres, which in ten specimens I have found to vary between 153 and 159, thus quite the same as in the adult Conger; below 35 mm. the most posterior

myomeres cannot be counted with certainty, but the pigmentation is sufficiently characteristic.

In the accompanying table (Fig. 1) I give a graphic summary of the Conger larvæ taken on the two cruises of the *Thor*. Without further explanation, it will be evident from this table that the *youngest stages*, of 1–4 cm. in length, have *only* been taken on the summer cruise, the older intermediate stages, of 5–9 cm., *only* on the winter cruise, whilst the full-grown Leptocephali, of

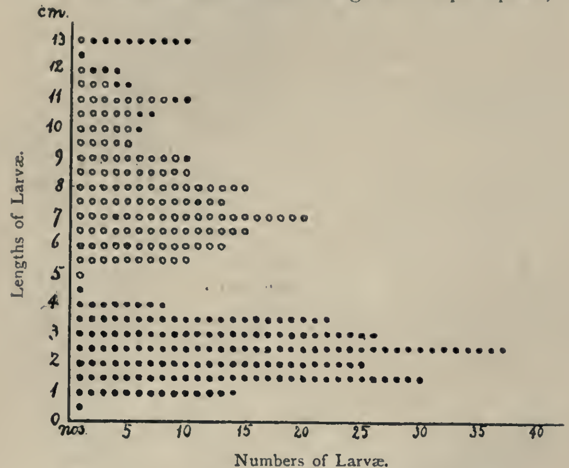

FIG. 1.—Conger larvæ. { • Summer cruise (vi, vii, viii). o Winter cruise (xii, i, ii).

ca. 12–13 cm. in length, were taken on both cruises, though mainly in the summer. From the sharp distinction between the youngest specimens taken on the summer cruise and the larger of the winter cruise, we are obliged to conclude that *the spawning of the Conger takes place mainly, if not exclusively, at a certain definite time of year, namely, in spring and summer.* We may further conclude from the material that the larval group of about 7 cm. is about half a year old, and that most of the larvæ of 12–13 cm., some of which are in process of transformation, are about one year old.

All the larvæ recorded in the table were taken in the Mediterranean or in the Atlantic off the Straits of Gibraltar. In earlier years (1905–8), when the *Thor* was working in the northern parts of the Atlantic, west of the British Isles, we also found several Conger larvæ during the period May to September, but these were all older stages, more than 12 and up to 16 cm. in length. The observations made on our last two cruises in the Mediterranean throw a new light on these older discoveries, for we now know that it is extremely easy to take the earliest Conger larvæ in the upper layers, when we know just *where* to find them. We may, in fact, conclude, with a high degree of probability, that the Conger does not spawn in the region examined by the *Thor* to the west of the British Isles, but further south in the Atlantic (Fig. 2, off the Straits of Gibraltar).

A more detailed account of the distribution of the different developmental stages will be given later, but on the accompanying chart I endeavour to summarise the occurrence of the youngest specimens, from 1–4 cm. long, all of which were taken on the summer cruise. It will be seen from this chart that *these earliest developmental stages were mainly taken over very great depths*, outside the 2000-metre line (or near this), but not in the many hauls which were made in the shallower waters. It appears, further, that the largest hauls (including newly hatched larvæ) were made at the deepest places the *Thor* had visited, namely, over depths of more than 3000 metres or about 3000 metres, in the Levant, the Ionian and Tyrrhenian Seas, as also in the deep basin between Sardinia and the Balearic Isles, where we have taken twenty to sixty larvæ in quite short hauls with pelagic apparatus.

These discoveries show that, when the time for reproduction arrives, *the Conger seeks out from the coasts to great depths, where it spawns mainly in the deepest and most central parts of the basins.*

In an earlier paper (1906) I suggested that the youngest larval stages of the eels might be bathypelagic, that is to say, living at great depths below the surface. Perhaps our most important discovery now is that *the earliest pre-leptocephalous stages of the Conger, as well as of the other four to five species the earliest larvae of which I know, really belong to the upper layers.* This can be seen from the hauls at any of our stations where such eel larvæ were taken in quantities. Our practice at each station was to make a series of hauls at varying depths, the length of wire out being 25, 100, 300, 1000, and 2000 metres, and the large quantities of the fry and eggs were always taken in the first, but few, or none at all, in the others. As the depth fished in could not have exceeded 15 metres, we must conclude that the youngest stages and the eggs belong normally to the uppermost layers of water. The older stages (Leptocephali), on the other hand, are also found in greater depths, 100–200 metres below the surface, as I have already shown in my earlier papers, and the life-history of the eel larvæ is thus no exception to the general rule applying to fishes with pelagic eggs, namely, that the earliest stages are passed at or near the surface, and that as development proceeds the larvæ sink down into greater depths.

The renowned Straits of Messina have also become famous in connection with our present subject as the first place where eel larvæ were found. So far as I know, the eel larvæ have never before been discovered in any quantity in the open waters of the Mediterranean, and this is the reason, I believe, why the reputation which the Straits of Messina obtained through the discovery of the Leptocephali there was, to a great extent, undeserved; in any case, the theories which the Italian observers founded on this discovery regarding the bathypelagic or demersal mode of life of the pre-Leptocephali and Leptocephali cannot be maintained. The conditions in the Straits where deep-sea forms and surface forms occur together at the surface are exceptional and abnormal, and the phenomena, biological and physical, we find there are not at all indi-

FIG. 2.—Chart of the Mediterranean and Atlantic, showing where the Conger larvæ were taken.

cative of the ordinary course of events. The pre-Leptocephali and the Leptocephali are just as much pelagic animals as, for example, the larvæ of the cod or haddock, and occur in the upper layers not exclusively in the Messina Straits, but everywhere in the various deep basins of the Mediterranean, as well as in the Atlantic.

With regard to the actual spawning of the eels, it is still undecided whether this takes place on the bottom or bathypelagically in great depths of the ocean. In our 1906 cruise we found the Leptocephali of the common eel in great numbers far out in the Atlantic over depths of 4000–5000 metres. Further, the largest quantity of murænoid eggs I have taken were found near the surface in the middle of the Tyrrhenian Sea over about 3500 metres. There is the possibility, therefore, that the eels seek out to these great depths in order to spawn bathypelagically, irrespective of the bottom, but unfortunately it will be very difficult to decide this question one way or the other.

Our present knowledge of the life-cycle of the eels may be summarised as follows.[1]

The eel-fishes spawn in great depths, how far from the surface we do not yet know. The eggs occur pelagically in the surface layers, and there give rise to the pre-leptocephalous stages, which also belong normally to the uppermost layers over great depths. Their whole organisation also shows that the pre-Leptocephali, as well as the Leptocephali, are true pelagic organisms. The Leptocephali likewise belong to the upper layers (high up at night, lower down in the day time), but there is the difference that during their prolonged existence they spread over greater distances and are also found over shallower waters than the pre-Leptocephali.

The first stages in the transformation also proceed pelagically, but thereafter the different species behave differently. Whilst some species during transformation go deeper down in the sea (*e.g.* Synaphobranchus), others (*e.g.* Conger and the common eel) undergo most of their metamorphosis in the upper layers. In their later life the former live in great depths, the latter in shallower water near the coast, and even in fresh water. When the time for reproduction arrives, all descend again into the oceanic depths whence they came, spawn but once, so far as we know, and never return. JOHS. SCHMIDT.

Copenhagen, February 8.

[1] Four species of Leptocephali, one of Tilurus, and first and foremost the two Conger species (*C. vulgaris* and *C. mystax*) form the basis of this summary.

REPORT OF THE CARNEGIE FOUNDATION.

THE fifth annual report of the president of the Carnegie Foundation for the Advancement of Teaching covers the year ending September 30, 1910. The report is divided into two parts. Part i. pertains to the current business of the year; part ii. is a discussion of the relation of the college and the secondary school.

The report shows that the trustees had in hand at the end of the year funds amounting to 2,222,811*l.*, consisting of the original gift of 2,000,000*l.* par value of 5 per cent. bonds and 200,000*l.* accumulated surplus. The income for the year was 108,776*l.* During the year sixty-four retiring allowances were granted, of which forty-six were in accepted institutions and eighteen in institutions not on the accepted list.

In the first part of the report the president of the foundation follows up the bulletin on medical education by a paper on the relation of the university to the medical school, in which he directs attention to the responsibility attaching to any college or university which undertakes medical education.

The second part of the report is a careful attempt to state the existing causes of friction between the secondary school and the college, and the loss of educational efficiency in the present methods of bringing pupils from the school to the college. The complaint of the college against the secondary school, and the complaint of the secondary school against the college, are set forth.

An extremely interesting part of the report is a statement of the observations of Oxford tutors upon the preparation of the Rhodes scholars. The strong points in the American youth's preparation are readily seen by these trained teachers, and the weaknesses which they find point directly to the superficiality and diffusion of the work done in the American secondary school and college.

The president of the foundation urges that this whole question be approached by secondary-school men and college men in a spirit of cooperation. Neither the certificate method of admission nor the piecemeal examination method have in his opinion solved the problem. He urges that the college must find a solution which will test better than the certificate or the piecemeal examination the fundamental qualities of the student, and which will at the same time leave to the high school a larger measure of freedom. He recommends a combination of certificate and examinations, the latter of a simple and elementary character, but calling for a high quality of performance, without which the candidate will not be admitted. For example, under this plan the boy who cannot write good idiomatic English would not be admitted to college at all, but would be sent back to the secondary school. The entrance requirements recently adopted at Harvard are quite in line with these recommendations. The president of the foundation urges a cooperation between the secondary school and the college, not as unrelated institutions, but as two parts of a common system of education. He argues that the interest of the great mass of high-school students must not be sacrificed to the interest of the minority who are looking toward college. He insists on a larger measure of freedom for the secondary school, but, on the other hand, he argues that the interest of the boy who goes to college and of the boy who goes from the high school into business are alike conserved by learning a few things well, not by learning many things superficially. The boy who has obtained such intellectual discipline is a fit candidate for college, whether he has studied one set of subjects or another; without this intellectual discipline he is unfit alike for college or business. It is therefore, in the opinion of the president of the foundation, the plain duty of the college, at the present stage of American educational development, to articulate intimately with the four-year high school and to leave to the secondary school the largest freedom so that it may educate boys, not coach them, but at the same time to require of the candidates for admission tests which rest upon high performance in the elementary studies and which mean mastery of the fundamentals. In such a programme lies the hope of scholarly betterment and of civic efficiency both for college and high school.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

BIRMINGHAM.—The legacy of 20,000*l.* bequeathed by the late Mr. John Feeney has been applied to the endowment of the chair of metallurgy, which is henceforth to be known as the "Feeney Chair of Metallurgy."

The Huxley lecture for this year is to be delivered by Prof. Henri Bergson, lecturer in philosophy at the University of Paris.

In addressing the Court of Governors at the annual meeting, the Vice-Chancellor referred with satisfaction to the recent grant of an additional halfpenny rate by the City Council, "which they all acknowledged had been generous." The principal (Sir Oliver Lodge) in his speech, which followed that of the Vice-Chancellor, defended the University against the charge of extravagance which had been brought against it in some quarters. He pointed out that "in this country we are behind in educational matters, and have been excessively economical when we ought to have been lavish in outlay." He stated that certain departments are better equipped in other modern universities in England, and that it must not be assumed that what Birmingham had done was "to be regarded as something out of the way and extraordinary." He also expressed the opinion that "it was highly important that universities, whatever aid they received, should not become appendages of State departments of the Civil Service. All our modern universities were experiments started by the nation in higher education, and no Government office or official was competent to control the highest education in the country. The only reasonable way was to trust the institutions and the experts called

together to manage them, because there were no better men, and though they made mistakes, it was better that such mistakes should be made individually than all over the country."

Cambridge.—The council of Trinity College has resolved to offer to the University the sum of 1000*l*. in the present year, to be invested for maintenance of buildings. The offer is made in the hope of expediting the erection of one or both of the proposed new buildings for physiology and experimental psychology.

The general board of studies will shortly proceed to appoint a university lecturer in moral science in succession to Dr. Keynes. The appointment will date from October 1. Candidates are requested to state the subject or subjects on which they are prepared to lecture. They are also requested to send their applications, with such testimonials as they think fit, to the Vice-Chancellor on or before Monday, April 24.

The Allen scholarship has been awarded to Mr. Hugh F. R. Smith, of St. John's College.

The next combined examination for sixty-eight entrance scholarships and a large number of exhibitions, at Pembroke, Gonville and Caius, King's, Jesus, Christ's, St. John's, and Emmanuel Colleges, will be held on Tuesday, December 5, and following days. Mathematics, classics, and natural sciences will be the subjects of examination at all the above-mentioned colleges. Most of the colleges allow candidates who intend to study mechanical sciences to compete for scholarships and exhibitions by taking the papers set in mathematics or natural sciences.

It is announced in *The Pioneer Mail* that his Highness the Nawab of Rampur has contributed a lakh and a half to the funds for the proposed Mahomedan University. At a meeting in Calcutta on February 14 last, his Highness the Aga Khan stated that the whole amount of money required is likely to be subscribed before the end of the present month, by which date it is expected the fund will exceed twenty lakhs.

The London County Council has issued a full report of the proceedings at the conference of teachers held under its auspices on January 5–7 this year. A descriptive account of the meetings of the conference was given in these columns on January 12 last (vol. lxxxv., p. 353), and it will be sufficient to point out that this official publication contains a verbatim report of the papers read and the discussions which took place. Copies of the report may be obtained from Messrs. P. S. King and Son, 2 and 4 Great Smith Street, London, S.W., price 1*s*. 6*d*.

We learn from *Science* that Dr. and Mrs. Robert W. Long, of Indianapolis, have given 40,000*l*. to the medical department of Indiana State University; that by the will of Mrs. Emily H. Moir, of New York City, Barnard College received 2000*l*.; and that Illinois College, at Jacksonville, Ill., received recently 1000*l*. from Mr. Edward F. Goltra, of St. Louis. This contribution is towards a new endowment of 30,000*l*. which the college is raising. Mr. Andrew Carnegie has contributed one-half of the amount; friends and old students have thus far contributed about 13,000*l*.

The Education Committee of the County Council of the West Riding of Yorkshire has issued a pamphlet giving detailed information of the conditions under which it awards scholarships and exhibitions. Provision is made for every grade of education, and facilities are offered to make it easy for the ambitious boy or girl to proceed on the educational journey from the elementary school to the university or technical college, so far as his or her ability permits. The needs of both men and women have been borne in mind. County major scholarships of the estimated value of from 60*l*. to 65*l*. are tenable at universities or university colleges, and county art scholarships of the value of 60*l*. per annum are tenable at the Royal College of Art. There are in addition county technological scholarships, scholarships for women, coal-mining exhibitions, agricultural exhibitions, exhibitions for the blind, and travelling scholarships. The capacity-catching net is certainly thrown very wide in the West Riding, and there should be very few Yorkshire students of talent unable to proceed with their education through lack of means.

The Department of Agriculture and Technical Instruction for Ireland will, as in previous years, conduct courses of instruction for teachers during the coming summer. Among the courses arranged may be mentioned those in experimental science and laboratory arts; in domestic economy; in hygiene, sick-nursing, and housewifery; in manual training in wood and metal; in practical mathematics and mechanics; and in rural science. All the courses mentioned will be held in Dublin. Teachers who attend the courses of instruction regularly and punctually will, as a rule, be allowed a sum of 3*l*. 10*s*. towards their expenses while living at the centre, and those who travel more than twenty miles to the centre of instruction will be allowed, in addition, third-class railway fare for one return journey. Teachers desiring to take advantage of the courses must fill up and return the appropriate form of application not later than March 31 to the offices of the Department, Upper Merrion Street, Dublin.

Copies of the report of the librarian of Congress and the report of the superintendent of the library building and grounds for the fiscal year ending June 30 last have been received from Washington. The reports, which are bound together, make a volume of 305 pages. The grants for the administration of the library proper and the copyright office in connection therewith amount for the present year to upwards of 98,000*l*. The report shows that there was a marked increase in the size of the library during the year under review; 90,473 books were added, 6822 maps and charts, and 17,215 prints, in addition to the pieces of music and volumes on music. A very interesting description is provided respecting the accessions to the division of manuscripts, of which, the report says, a numerical estimate is not feasible. We notice that the total number of visitors to the library building during the year was 768,911, being a daily average for 363 days of 2118.

A gift of 60,000*l*. by Mrs. Russell Sage to Cornell University is announced in *Science*. From the same source we learn that an increase in the income and in the building fund of the University of Wisconsin on the basis of a growth of 23 per cent. in the number of students in the last two years and of the constantly growing demand on the part of the people of the State for expert assistance from the University, is provided for in a Bill introduced in the State legislature. It provides for changing the present two-sevenths of a mill tax on the assessed valuation of all property of the State for maintaining the University to three-eighths of a mill. This will increase the general University income approximately from 125,000*l*. a year to 200,000*l*. a year. For new academic buildings and permanent improvements, the proposed legislation appropriates 60,000*l*. a year, of which 10,000*l*. annually is set aside for the purchase of books, furniture, apparatus, and equipment. The remaining 50,000*l*. a year is to be used for the construction of academic buildings, in the order of their greatest need, and for the enlargement and repair of present buildings. The regents of the University of Michigan, too, have applied to the legislature for a grant of 50,000*l*. for a science building. The need for more adequate accommodations for the natural sciences has been felt for a number of years, and was the subject of a memorial to the regents by the departments of botany, zoology, geology, mineralogy, and forestry in 1907.

The distribution of prizes and certificates to students of the Battersea Polytechnic was held on Tuesday, February 28. The principal, Dr. Rawson, in presenting his report, stated that he thought in every respect the report was a satisfactory one, there having been a considerable increase in the student hours, these, on the whole, being the best criterion of the progress of an institution. The examination successes included nine passes for the final B.Sc., five being in honours; seven students passed the intermediate B.Sc., and three the engineering intermediate examination. The principal added that the work of the Day Technical College, both in quantity and quality, was steadily rising, and that a full four-year course was in operation. A very gratifying feature was the demand which was being experienced for their students, in almost all cases positions having been found for all three-year students by the end of the session. Dr. T. J. Macnamara,

M.P., in addressing the students, said that the English people are rapidly coming to see that in the markets of the world the schoolmaster is the agent in advance. Our great past, glorious as it was, may be something of a handicap if we slavishly follow the paths that led to our being a great people. The governing forces of the universe are changing with a rapidly increasing momentum. Brawn put us where we were, but, under present conditions, will not keep us there. Nowadays a nation, to maintain its place, must have brain as well as brawn.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, March 2.—Sir Archibald Geikie, K.C.B., president, in the chair.—Prof. C. S. **Sherrington** and Miss S. C. **Sowton**: Reversal of the reflex effect of an afferent nerve by altering the character of the electrical stimulus applied.—Dr. H. E. **Roaf**: Carbon dioxide output during decerebrate rigidity (preliminary communication). The object of this research is to determine the amount of energy required to maintain muscular rigidity in decerebrate cats. As an indication of the energy production, the carbon dioxide output was measured. The animals were maintained under constant conditions. The experiments were divided into two periods of two hours each. During the first period the carbon dioxide production of the decerebrate cats was measured, and during the second the carbon dioxide production, after abolishing the rigidity, was estimated. The results show that abolishing the rigidity by curare does not alter the carbon dioxide output, and hence there does not seem to be any more energy used to maintain the rigid condition than when the muscles are flaccid. Decapitation abolishes the rigidity, and at the same time lowers the carbon dioxide output. The cause of this lowering of the carbon dioxide output is being investigated.—Dr. Arthur **Harden** and W. J. **Young**: The alcoholic ferment of yeast-juice. Part vi.—The influence of arsenates and arsenites on the fermentation of the sugars by yeast-juice. The results of the investigation may be summarised as follows:—(1) When a suitable amount of arsenate is added to a fermenting mixture of yeast-juice and a sugar, it causes a large acceleration in the rate of production of carbon dioxide and alcohol. This enhanced rate differs from that produced by phosphate, inasmuch as it continues long after a chemical equivalent of carbon dioxide has been evolved. The arsenate, moreover, is found in the free state throughout the fermentation. (2) The rate attained increases rapidly with addition of arsenate until *optimum* concentration is reached, after which it decreases, at first rapidly and then more slowly. (3) The total fermentation produced depends on the particular concentration of arsenate employed, and may be either higher or lower than that given in the absence of arsenate. As the high rate produced by a suitable quantity of arsenate persists for a long time, very considerable increases in the total fermentation may be observed. (4) Glucose and mannose are similarly affected by yeast-juice in presence of arsenate, whereas fructose is much more rapidly fermented than these two sugars, and the optimum concentration of arsenate in its presence is greater. (5) The increased rate of fermentation of sugars in presence of arsenate is due to an acceleration of the rate of action of the hexosephosphatase of the juice, whereby an increased supply of phosphate is afforded. The action is therefore essentially different from that of phosphate, and it has been found that arsenate cannot replace phosphate in the fundamental reaction of alcoholic fermentation. (6) Arsenate also causes a considerable increase in the rate of autofermentation of yeast-juice and in the rate of fermentation of glycogen. This is mainly due to acceleration of the rate of action of the diastatic enzyme of yeast-juice (glycogenase). (7) The action of arsenites is similar to that of arsenates, but is much less marked. (8) Both arsenate and arsenite cause total inhibition of the fermentation when they are present in a high concentration, but the nature of this effect has not been ascertained.—Colonel Sir David **Bruce** and Captains A. E. **Hamerton** and H. R. **Bateman** (Sleeping Sickness Commission of the Royal Society, Uganda, 1908–10): Experiments to ascertain if certain Tabanidæ act as the carriers of *Trypanosoma pecorum*. In the latter part of 1909 the commission noted that an outbreak of cattle trypanosomiasis due to *Trypanosoma pecorum* at Mpumu, Uganda, coincided with the appearance of swarms of *Tabanus secedens* in certain places where the cattle went to graze. In 1910 the following researches were commenced to ascertain if *Tabanus secedens* might be the carrier of this trypanosome. An investigation of the biting flies occurring where the cattle became naturally infected showed twelve species of Tabanus, five species of Hæmatopota, two species of Chrysops, *Glossina palpalis*, and a new species of Rhinomyza. Before this investigation, it was thought that some five or six species comprised all biting flies inhabiting the locality. *Glossina palpalis* was found inhabiting an inland stream having no connection with Victoria Nyanza, and situated six miles from the lake shore. Tabanidæ appear suddenly in great numbers in certain localities for a few months only, then as suddenly disappear. Hæmatopota was found in open swampy places and forests. Chrysops and Rhinomyza were comparatively scanty; found about fords of streams in the forests. The three species *Tabanus secedens*, *T. fuscomarginatus*, and *T. thoracinus*, were the most common of the Tabanidæ. Their eggs or larvæ were never found, and only wild flies were experimented with. The flies would not live in cages. Transmission experiments were carried out in a fly-proof kraal built amidst the natural surroundings. Sick and healthy calves were daily placed together in a compartment of the kraal in which the above-named species were set free, the experiments being performed with only one species of fly at a time. The flies only lived a few days, but were frequently observed to bite the cattle. A control calf was kept in a compartment of the kraal, to which no flies had access. Large numbers of flies of the above-named species were used, but no normal calf contracted the disease. Two series of dissections were made. First, of the wild flies, obtained near the laboratory, the same day they were caught; secondly, of wild flies, introduced into the fly compartment of the kraal, after they had had the opportunity of biting the infected calf therein. In the first series 138 *Tabanus secedens* and 49 *T. thoracinus* were dissected. Of the former, 5 per cent. showed a heavy infection of flagellates in the hind-gut, rectum, and proctodæum only; of the latter, flagellates were found in hind-gut, rectum, and proctodæum of 25·5 per cent. Inoculation of these parasites into white rats failed to cause disease. In the second series, liberated in the fly compartment of the kraal, 50 *T. secedens*, 24 *T. thoracinus*, and 37 *T. fuscomarginatus* were dissected. Two *T. secedens* were infected with flagellates, and one *T. thoracinus*. None of the *T. fuscomarginatus* were infected. Inoculation of these parasites into white rats also failed to cause disease.—H. M. **Leake**: Experimental studies in Indian cottons.

Geological Society, February 17.—Prof. W. W. Watts, F.R.S., president, in the chair.—Annual general meeting.—Prof. W. W. **Watts**: Presidential address. The consideration of geology as geographical evolution. The main factors of the geographical evolution of an area were considered to be the alternation of upward and downward movement. Each geographical cycle, passing from the period of maximum depression through uplift into terrestrial conditions, and then back again towards depression and submergence, would be expressed in the geological record by a corresponding set of deposits consisting of "thalassic," "shoreward," "terrestrial," "estuarine," and "thalassic" deposits, following each other in this order. Each of these phases was considered in some detail, and attention was directed to difficulties in interpretation and correlation, and to the principles according to which the depositional phenomena should be translated into terms of geography. Despite the fact that several cycles of geography and deposition had swept over Britain, there had been comparatively little repetition of phase in the deposits, and two or three examples were taken to illustrate cases of correspondence and non-correspondence of deposits formed during similar stages in the succeeding cycles. The careful and minute study of existing geographical conditions was strongly advocated as the key to the interpretation of the geological record, and it was

urged that the utmost possible use should be made of palæogeographical maps, both as a means of expressing ascertained fact and as affording a focus for new critical investigation. The association of the phases of earth-movement with igneous activity was next briefly treated, as also the connection of movement with rock-structure and existing physiography. Finally, geographical evolution was examined as the spur to organic evolution, and it was urged upon palæontologists that they should endeavour to ascertain to what extent periods of slow or rapid evolution corresponded with epochs of physical change.

February 22. Prof. W. W. Watts, F.R.S., president, in the chair.—R. H. **Rastall**: The geology of the districts of Worcester, Robertson, and Ashton (Cape Colony). After a brief description of the physiography of the district and the general sequence of the rocks composing it, in which the incompleteness of the stratigraphical record is especially noted, a detailed account is given of the structure and characters of the Malmesbury rocks of Worcester and the region near that town. These are shown to include a lower and an upper sedimentary series, predominantly gritty and slaty respectively, and evidently of great thickness, probably more than 20,000 feet. The upper division is pierced by granitic dykes, which have been subsequently crushed and foliated, forming "phyllite gneiss." Certain bands of limestone are metamorphosed by them to pure white marble. The distribution and characters of the rocks of the Cape and Karroo systems are only dealt with, in so far as they throw light on the principal subject of the paper, but a fairly full description is given of the occurrences of Enon Conglomerate, which is shown to occupy a series of isolated basins arranged along an east-and-west line, and to lie with a strong discordance upon all the older rocks. After a careful discussion of all the available evidence, it is concluded that the Worcester-Swellendam Fault, which has a maximum throw of probably 10,000 feet, is in great part of post-Cretaceous age, although there are indications of earlier movement along the same line of fracture. From a study of the dominant trend-lines of south-western Cape Colony, it is concluded that the district in question is situated at or near the central line of the syntaxis of two great sets of folds at right angles, which have assumed a fan-shaped arrangement in plan, and that the great fault is a line of fracture and subsidence running transversely across these lines of folding.—Baron Ferencz **Nopcsa**, jun.: Geology of northern Albania. The author had examined the greater part of the province of Skutari in western Turkey, and recognised three distinct structural units, namely, the north Albanian platform, the folded Čukali, and the eruptive region of Merdita. In the first region Mesozoic limestone of all periods predominates, in the second region Mesozoic radiolarian chert is found, while in the third region Mesozoic clastic rocks, volcanic tuffs, and eruptive masses are abundant. The first and third units are not folded, but are, at least in part, overthrusts from the north and south respectively above the second (intermediate) unit, which is strongly folded. In northern Albania Upper Carboniferous and Permian rocks are also distinguishable, and there is an Eocene flysch.

Zoological Society, February 21.—Dr. A. Smith Woodward, F.R.S., vice-president, in the chair.—R. **Lydekker**: *Tragelaphus buxtoni*, an antelope obtained by Mr. Ivor Buxton in Abyssinia.—E. G. **Boulenger**: Varieties of the spotted salamander (*Salamandra maculosa*). One of the principal results of the author's study was to lay greater stress on the disposition of the spots than on their actual form, size, or colour, and to define two principal forms in Central Europe, which had not previously been separated with sufficient precision, notwithstanding their well-marked geographical distribution. The author further dealt with some of the experiments of Dr. Kammerer, of Vienna, and the conclusions arrived at by him with regard to coloration in relation to environment.—G. A. **Boulenger**: A collection of fishes from the Lake Ngami basin, Bechuanaland, made by Mr. R. B. Woosnam.—Dr. F. D. **Welch**: Gibbons of the genus Hylobates, and on a Siamang gibbon, recently living in the society's gardens, with notes on skins in the British Museum (Natural History).

MANCHESTER.

Literary and Philosophical Society, February 21.—Mr. Francis Jones, president, in the chair.—Dr. Alfred **Holt**: The boric acids. Experiments were described on (1) the rate at which orthoboric acid loses water when heated to different temperatures; (2) the changes in the vapour density of orthoboric acid on heating; (3) the freezing points of solutions of ortho-, meta-, and pyroboric acid; and (4) melting points of mixtures of orthoboric acid and boric anhydride. From these experiments the following conclusions were drawn:—(1) metaboric acid is probably a definite compound; (2) no evidence is found for the existence of boric acids containing less water than the meta acid; (3) only orthoboric acid exists in solution, and it is present in simple molecules; (4) metaboric acid cannot be regarded as an equimolecular mixture of orthoboric acid and boric anhydride; (5) fused mixtures of orthoboric acid and boric anhydride, in which the molecular ratio of the latter to the former compound exceeds 4:1, can exist in a vitreous metastable and crystalline stable form.—J. E. **Myers** and Dr. A. **Holt**: The hydration of metaphosphoric acid. Experiments were described by which it was shown that pyrophosphoric acid is formed as an intermediate compound in the hydration of metaphosphoric acid. It was further shown that the hydration did not take place according to any simple scheme, and a method of estimating meta acid in a solution of all three varieties by means of barium chloride was described. From the depression of the freezing point of aqueous solutions of various varieties of pyro and meta acids, it appears that, when these acids are prepared by dehydration of orthophosphoric acid, there occurs association of the molecules, but when prepared by decomposition of the lead salts by hydrogen sulphide, simple molecules result. The peculiar "crackling" phenomenon which accompanies the solution of one form of meta acid was shown.

DUBLIN.

Royal Irish Academy, February 11.—Dr. F. A. Tarleton, president, in the chair.—W. M'Fadden **Orr**: Extension of Fourier's and the Bessel-Fourier theorem. The author shows by application to some illustrative physical problems how certain defects as to uniqueness and differentiability in the expansions of the former paper (Proc. Roy. Irish Acad., vol. xxvii., A, 11) may be remedied. These problems include the motion of the system consisting of a stretched elastic string and a number of elastically connected particles at each end, in extension of a simple case considered by Lord Rayleigh ("Theory of Sound," § 135), the analogous problem involving the motion of a circular or annular membrane, and analogous problems in heat conduction. The expansions are also extended so as to apply to the same vibrating systems when subject throughout to viscous forces, in which case the displacement of the string satisfies the equation

$$d^2\phi/dt^2 = c^2d^2\phi/dx^2 - fd\phi/dt + gd^3\phi/dx^2dt.$$

—A. W. **Conway**: The application of quaternions to some recent developments of electrical theory. Two examples of quaternion treatment are given for the purpose of showing the superiority of this method over vectors, by considering two cases in which the latter would lead to great complication. The subjects taken are Poincaré's Fredholm solutions for Hertzian waves, and Einstein's and Minkowsky's formulæ of relativity.—Rev. M. F. **Egan**: The linear complex and a certain class of twisted curves on twisted curves such that the degree of any cycle of the curve is equal to its class. Relations between such curves and null-systems in three-space.

February 27.—Dr. F. A. Tarleton, president, in the chair.—R. Lloyd **Praeger**: Clare Island survey: report of progress during 1910. During the second year's field work on Clare Island and its neighbourhood great advances have been made. About fifty workers visited the district during the year, for periods ranging from one to three weeks. Simultaneously with this report, the first instalment of the results of the survey are presented to the academy. It is intended to finish the field-work during the present year. In connection with the Clare Island survey, the following papers were read:—N. **Colgan**: Marine mollusca. The author gives a very full account of the marine mollusca collected during the years 1909 and

1910 in the various dredgings and shore collectings made in the Clew Bay area. The list includes 246 species, and of these no fewer than 133 were taken in a single haul of the dredge. Amongst the species enumerated are two nudibranchs, here for the first time recorded as Irish, *Thecacera pennigera* and *Actaeonia cocksii*. New records are also given for many rare species, the most interesting being *Circulus striatus* (*Trochus duminyi*), which was twice dredged in the bay.—J. N. **Halbert**: Water mites. At least four species previously unknown to science, and ten others new to the British Islands, are recorded.—H. Wallis **Kew**: False scorpions.—James **Wilson**: Agriculture and its history. The initial purpose of this paper is to determine the approximate dates at which agricultural plants and animals, not native to the island, might have been introduced. To do this, it is necessary to consider the history of agriculture first of all in Ireland, and then in Great Britain and the neighbouring Continent, in order to trace the immigration of their plants and animals westwards. The paper becomes, therefore, a concise historical note on British and Irish agriculture, with special regard to such data as bear upon its initial purpose.—N. **Colgan**: Irish names of animals and plants. The writer has collected on Clare Island and about Clew Bay current Gaelic names for about 120 species of native plants and animals. The dialectic variants found in use in other parts of Ireland are appended to those collected in the Clew Bay area, and supplementary notes are added on the folk-lore found in association with certain of the animals and plants referred to.

Paris.

Academy of Sciences, February 20.—M. Armand Gautier in the chair.—J. **Carpentier**: Remarks on a modified pattern of the spherometer due to M. Nugues.—M. Eugène Tisserand was elected a member of the section of free academicians, in the place of the late M. J. Tannery.—Carl **Störmer**: The structure of the solar corona. Calculations have been made for a series of trajectories of electrified corpuscles, emanating normally from the solar surface, and assuming that the magnetic field of the sun is identical with that of an elementary magnet placed at the centre with its axis along the axis of rotation. The results of these calculations are shown graphically, and compared with the form of the corona at the time of minimum sun-spot frequency.—Maurice **Gevrey**: Partial differential equations of the parabolic type.—A. **Buhl**: The geometrical application of the formula of Stokes.—Ed. **Sarasin** and Th. **Tommasina**: The action of slight elevations of temperature on induced radio-activity. From the experiments described, it is concluded that even small elevations of temperature act on metals which have been rendered radio-active, causing an immediate and temporary increase in their loss of activity.—F. **Leprince-Ringuet**: The law of transmission of heat between a fluid in motion and a metallic surface.—Paul **Lebeau**: Uranyl nitrate and the nature of its ethereal solution. The uranyl salt forms a compound with the ether used for its solution, and there is a slight heat evolution. This compound can be crystallised out by cooling the solution with a mixture of solid carbon dioxide and acetone.—V. **Auger** and M. **Gabillon**: A new method for the estimation of sulphuric acid and sulphates. The sulphate is distilled with a mixture of potassium iodide, phosphoric, pyrophosphoric, and phosphorous acids. The sulphur is given off quantitatively in the form of sulphuretted hydrogen, the latter being absorbed and estimated in the usual manner. The method fails with barium sulphate.—G. **Darzens**: Condensation of halogen derivatives with $\beta\beta$-dimethylglycidic ester. Dimethylglycidic ester, treated with zinc and an alkyl iodide, gives substituted lactic acids of the general formula $Me_2.CH.CR(OH).CO_2H$, and from these, by dehydration, a series of unsaturated acids can be obtained.—E. E. **Blaise** and L. **Picard**: The action of the chlorides of the α-alkoxylacids on the mixed organo-derivatives of zinc.—A. **Guilliermond**: The reproduction of *Debaryomyces globosus* and on some phenomena of retrogradation of sexuality observed in yeasts. These yeasts form one of the best examples known of a group in the course of evolution towards parthenogenesis.—Mlle. G. **Promsy**: The influence of acidity on germination.—M. **Mazé**: The excretion of mineral and organic substances by roots and stomata.—R. **Legendre** and H. **Piéron**: Experimental contribution to the physiology of sleep. The authors' experiments lead them to the conclusion that there exists in the cerebral plasma, blood, and especially in the cephalo-rachidian fluid of dogs suffering from insomnia, a substance possessing a hypnotoxic property. This disappears when heated to 65° C., and causes an overpowering demand for sleep.—M. **Piettre**: Muscular autolysis of pathological origin.—Paul **Hallez**: A non-parasitic Bdelloura of the Antarctic seas.—Jean **Effront**: The Bulgarian ferment. A comparison of total and volatile acids produced by the action of seven Bulgarian ferments of different origin shows that the bacterium isolated by Bertrand is clearly differentiated from the rest. This ferment produces more total acid and less volatile acids than any of the others.—H. **Bierry**: The digestive ferments of manninotriose and its derivatives.—J. L. **Dantan**: Fecondation in *Paracentrotus lividus* and *Psammechinus miliaris*.—Raphael **Dubois**: The disease affecting crayfish in the lake of Nantua. The malady is shown to have been caused by a yeast, *Rhabdomyces Duboisii*.—Jules **Amar**: The expenditure of energy in walking. The energy expenditure depends on several factors, speed, rhythm, displacement of the centre of gravity, oscillations of the body, &c., and follows no simple law. The effect of carrying a load has been studied, and also the most economical speed for walking.—Léon **Bertrand**: The prolongation of the North Pyrenees sheets in the western Pyrenees.

February 27th.—M. Armand Gautier in the chair.—A. **Chauveau**: The phenomena of visual inhibition which may accompany the re-association of the two retinal images dissociated by the prisms of the stereoscope. Some experiments on stereoscopic vision with most interesting results are described in detail. The inhibiting action of one eye on the other is most strikingly shown in one experiment. When the left eye is cut off by a screen all the details of the figure are clearly seen with the right eye; on removing the screen all the details of the figure disappear.—A. **Laveran** and A. **Thiroux**: The identification of the pathogenic trypanosomes. An examination of the method proposed by Levaditi and Mutermilch, and based on the attachment of the trypanosomes to leucocytes. It has been found that although the method yields useful indications, it cannot be relied upon for an absolute diagnosis.—E. L. **Bouvier**: Observations in the Pycnogonomorphs and principally on *Pentapycnon Geayi*.—Paul **Sabatier** and A. **Mailhe**: Direct esterification and saponification by catalysis (see p. 54).—Jean **Chazy**: The determination of uniform functions in the neighbourhood of points where they cut.—S. **Bernstein**: The approximation of continued functions by polynomials.—C. **Cailler**: The linear pentaseries of solid bodies.—M. **d'Ocagne**: The nomographic determination of the path pursued by a ship in the course of varied movement.—M. **Bertin**: Observations on the preceding note.—Jean **Becquerel**: The duration of the phosphorescence of the uranyl salts. The duration of the phosphorescent emission is independent of the temperature (down to −193° C.) for uranyl sulphate and nitrate, whilst uranyl acetate, tartrate, oxalate, and other organic salts follow the ordinary rule, and the phosphorescence is of longer duration at the lower temperatures.—Henri **Abraham**: Relays and electric servo-motors.—M. **Ferrié**: The measurement of the lengths of Hertzian waves. Various types of wave meters are indicated and full particulars given of the method of calibration of one of them.—L. **Gay**: Mixtures of acetic acid with normal liquids.—Eugène **Fouard**: A practical method for the preparation of semi-permeable membranes applicable to the measurement of molecular weights. The method is based on the use of a collodion membrane, prepared according to the description of E. Roux and Salimbeni; this is permeable to a true solution but impermeable to the ultra-microscopic particles of a colloid. If such a collodion tube containing a tannic acid solution is placed in a gelatine solution, the membrane is modified in such a manner that whilst remaining freely permeable to water, it becomes impermeable to substances such as sugar in solution, and thus fulfils the condition of a semi-permeable membrane. Such a cell can be used to prove that two solutions are isotonic with much greater accuracy than is obtained by the method of de Vries.—

Daniel **Berthelot** and Henry **Gaudechon**: Nitrification by the ultra-violet rays. An aqueous solution of ammonia under the action of ultra-violet light forms some nitrite. A solution of ammonium nitrate under similar conditions gives off oxygen mixed with nitrogen and nitrite is formed. The effects of ultra-violet light are generally similar to those of ferments.—Emile **André**: The combination of amines with acetylenic ketones. The preparation of β-substituted ethylenic aminoketones.—Charles **Moureu** and Amand **Valeur**: Isosparteine, a case of stereoisomerism of nitrogen.—Henri **Coupin**: The comparative toxicity of plant essences on higher plants. The action of the essential oils from a large number of plants has been studied from the point of view of their action on wheat germs. The great majority prove to have clearly toxic effects.—G. **Gastine**: The use of saponins for the preparation of insectidal emulsions and liquids for the destruction of insects and cryptogams. The addition of saponin to such liquids is shown to be distinctly advantageous.—Henri **Bierry**, Victor **Henri**, and Albert **Ranc**: The action of ultra-violet light on glycerol.—J. **Renaut**: Mitochondria of the globular cells of the hyaline cartilage of mammals.—Ph. **Négris**: The existence of the trias at Mt. Ktypas (Messapion) and the importance of the gap between the Trias and the Cretaceous in Greece.

DIARY OF SOCIETIES.

THURSDAY, MARCH 9.

ROYAL SOCIETY, at 4.30.—(1) The Absorption Spectra of Lithium and Cæsium; (2) Dispersion in Vapours of the Alkali Metals: Prof. P. V. Bevan.—On the Ionic Solubility-product: J. Kendall.—Note on the Electrical Waves occurring in Nature: Dr. W. H. Eccles and H. M. Airey.—The Action of Animal Extracts on Milk Secretion: Prof. E. A. Schäfer, F.R.S., and K. Mackenzie.

MATHEMATICAL SOCIETY, at 5.30.—On the Reduction and Classification of Binary Cubic Forms which have a Negative Determinant: G. B. Mathews.

INSTITUTION OF ELECTRICAL ENGINEERS, at 8.—The Laying and Maintenance of Transmission Cables: C. Vernier.

SOCIETY OF DYERS AND COLOURISTS, at 8.—The Fading of Dyestuffs: J. W. Lovibond.

FRIDAY, MARCH 10.

ROYAL INSTITUTION, at 9.—Recent Advances in Turbines: Hon. C. A. Parsons, F.R.S.

ROYAL ASTRONOMICAL SOCIETY, at 5.—On the bearing of the Principle of Relativity in Gravitational Astronomy: W. de Sitter.—The long-period Variable *RT* Cygni: A. N. Brown.—On a New Family of Periodic Orbits in the Problem of Three Bodies: E. W. Brown.—On the Determination of the Places of Reference Stars and Fundamental Stars by Photographic Methods: H. H. Turner.—On the Oscillating Orbits about the Triangular Equilibrium Points in the Problem of Three Bodies: E. W. Brown.—On the Problem of Distribution in Globular Star Clusters: H. C. Plummer.—Measures of Double Stars: Royal Observatory, Edinburgh.

MALACOLOGICAL SOCIETY, at 8.—On the Recent Species of Vulsella; on a New Species of Phasianella: E. A. Smith.—On the Value of the Gasteropod Apex in Classification: T. Iredale.—*Valvata Woodwardi*, n.sp., and *Sphærium Bulleni*, n.sp., from the Forest Bed (Cromerian) of West Runton, Norfolk: A. S. Kennard.

PHYSICAL SOCIETY, at 8.—Demonstration of the Working of the Gyro Compass: G. K. B. Elphinstone.—Note on an Electrical Trevelyan Rocker: Dr. W. H. Eccles.—Notes on the Tilted Gold-leaf Electroscope: Dr. G. W. C. Kaye.

SATURDAY, MARCH 11.

ROYAL INSTITUTION, at 3.—Radiant Energy and Matter: Sir J. J. Thomson, F.R.S.

MONDAY, MARCH 13.

ROYAL GEOGRAPHICAL SOCIETY, at 8.30.—A Pioneer Journey in the Purcell Range, British Columbia: Dr. T. G. Longstaff.

ROYAL SOCIETY OF ARTS, at 8.—Applications of Electric Heating: Prof. J. A. Fleming, F.R.S.

TUESDAY, MARCH 14.

ROYAL INSTITUTION, at 3.—Crystalline Structure: Mineral, Chemical, Liquid: Dr. A. E. H. Tutton, F.R.S.

ILLUMINATING ENGINEERING SOCIETY, at 8.—*Resumed discussion* on School Lighting.

INSTITUTION OF CIVIL ENGINEERS, at 8.—The Electrification of a Portion of the Suburban System of the London, Brighton and South Coast Railway: P. Dawson.

FARADAY SOCIETY, at 8.—Some Properties of Aluminium Anode-films: G. E. Bairsto and R. Mercer.—The Weight of a "Normal" Litre of Hydrogen Chloride and the Atomic Weight of Chlorine: F. P. Burt and Dr. R. W. Whytlaw-Gray.—A Physico-chemical Study of Mercury-sodium Alloys or Sodium Amalgams: E. Vanstone.—On Surface Effects between Mercury and certain Solutions, and an Electro-chemical Method of Estimating Dissolved Oxygen: Dr. S. W. J. Smith and W. F. Higgins.

WEDNESDAY, MARCH 15.

ROYAL INSTITUTION, at 3.—Radiant Energy and Matter: Sir J. J. Thomson, F.R.S.

CONTENTS.

THURSDAY, MARCH 16, 1911.

THE KAISER-WILHELM SOCIETY FOR THE PROMOTION OF SCIENCE.

GERMANY, and its head, the Emperor, have again shown the world their gratitude for the achievements of science; if desired, the word gratitude may be interpreted in the sense of "favours to come." Not content with endowing the universities and technical high schools from the Exchequer with what appear to us relatively enormous sums, a society has been founded, under the "protection" of the Emperor, for the advancement of science. It is instructive to note the difference between their method and ours. Both countries possess what is called "technical education"; but while we have founded schools in considerable number, destined to capture the workmen (who seldom attend) and the prospective foremen, they have aimed at the education of the manufacturers and the works managers. Instead of numerous institutions giving elementary science instruction, they have a few, imparting the most advanced. Instead of a system of small scholarships, intended to bribe the clever children of the lower middle class, they leave it to the parents to find out that their children, suitably trained, are equipped for their lifework, and will, if they are diligent, be certain of reasonable incomes, and respectable positions.

In this latest enterprise, too, the Germans have appealed, not to the moderately well-off, but to the rich. Membership of the new society may be acquired by private persons, or by firms, on the condition of an initial contribution of 20,000 marks (1000*l.*), payment of which, by special resolution of the Senate, may be distributed over several years, and besides this, an annual contribution of 1000 marks a year, commutable by a lump sum of 40,000 marks, or 2000*l.* The members are to be elected by the Senate, a body chosen by themselves at a general meeting, which must be held once each year, in February, but may be summoned also at any time by the president, or by any two members. Members of the Senate, consisting of at least ten members chosen by the contributors, hold office for five years; to it belong other members, not necessarily donors but *Gelehrte, i.e.* savants, or other persons who may be deemed useful, nominated directly by the Protector, that is, by the German Emperor. The election of members by the Senate requires the Protector's confirmation before it becomes absolute. Rules exist for the resignation of members and for the removal of defaulting members. The Senate meets twice a year, and holds a statutory meeting in March; it may also be summoned at other times by the Protector, by its Executive Committee, or by request from a third of its members. It elects a president, two vice-presidents, two treasurers, and two secretaries; the election of the three first also requires confirmation by the Protector. These form the executive committee of the society.

The object of the society is designated in its title, and in its first statute; it is "to promote the sciences, especially by the foundation and support of scientific institutes of research."

Readers of NATURE will have already read a translation of the address delivered at the opening of the society in presence of its Protector, by Prof. Emil Fischer, of Berlin, printed in the issue for February 23. The daily papers have informed us that at the celebration of the centenary of the Berlin University held last October the Emperor announced that this society had at its disposal a capital of half a million sterling. It is proposed to devote its income to the equipment of institutes in which men already eminent in their respective subjects will be installed. They will have the right to take student-assistants, *i.e.* young men, who wish to graduate in one or other of the universities; they will thus be able to pursue research, aided as much or as little as they please. Such a position was held, as member of the Berlin Academy, by Prof. van't Hoff, whose recent removal by death the whole scientific world deplores. He had a free hand, was not obliged to give any formal lectures, or to take part in the active management of the University, but was allowed, with the help of students, to work out his own problems in his own way, and his work on Stassfurth salts has been of great technical value. His words to the writer were, many years ago, that he thought it right to help his adopted country to solve its commercial problems, and that he had attempted to do so. But it must be understood that no such expectation is necessarily entertained of the incumbents of chairs at the proposed institutes; the progress of *science*, not necessarily of its industrial application, is contemplated. Our neighbours have learned the lesson that science, like virtue, brings its own reward.

It is wonderful how deeply the spirit of trust in science has penetrated the whole German nation. When Prof. Ostwald, many years ago, appealed to the Saxon Government for money to build his physico-chemical laboratory, the Socialists in the Saxon Parliament voted for the grant to a man, believing that greater expenditure on pure science would contribute to greater industrial opportunities. This spirit, which permeates the German people, from the Emperor on his throne to the representatives of the peasants, causes admiration; would that it could inspire imitation!

One is led to speculate on the cause of this. Why is it that the people of Germany have such sympathy for scientific endeavour? The reasons are many.

First, and above all, is the discipline which the German people have undergone by their military training; more are thus prepared for practical life in a measure which cannot be otherwise attained. It has its disadvantages; on the whole, the people are not so self-reliant, but they become more trustworthy machines. Second, there is a deeper understanding of scientific achievements and their bearing on industry. This manifests itself in many ways; the German Government is not above asking for, and acting on, scientific advice. The social position of the savants, scientific and literary, is therefore assured, and the incomes of the higher posts compare favourably with those earned by professional men and manufacturers. This higher social standing secures attention to those who tender advice. Third, there is a constant ex-

change between academic and industrial posts; many men leave chairs to become managers of factories; many men enter the teaching and investigating profession from factories. Chemical and physical factories, too, there form a training school for the younger scientific experts; where many are employed, the more advanced communicate their knowledge and the results of their experience to the junior members of the scientific staff; in fact, they have apprenticeship at its best. Here, in prosperous times, the manufacturer thinks that he has no need of scientific assistance; in times of bad trade he believes that he cannot afford it. And, lastly, the process of training the people has gone on in Germany for nearly a hundred years. Rewards have been given, not to successful examiners, and not in the form of scholarships; but have been earned in the battle of life, for which ample preparation has been given.

This spirit of trust in science has permeated to the highest in the land; that it has been fertile in practical results is amply proved by the inception of the Kaiser-Wilhelm Society for the furtherance of science.

MIMICRY IN THE BUTTERFLIES OF AFRICA.

African Mimetic Butterflies; being Descriptions and Illustrations of the principal known instances of Mimetic Resemblance in the Rhopalocera of the Ethiopian Region, together with an Explanation of the Müllerian and Batesian Theories of Mimicry, and some account of the Evidences on which these Theories are based. By H. Eltringham. Pp. 136+x plates and map. (Oxford: Clarendon Press, 1910.) Price 50s. net.

THIS valuable work is in chief part devoted to the "Descriptions of Mimetic Associations in African Rhopalocera," illustrated by nine beautiful coloured plates (ii–x) and by a most useful map of Africa. This—the main object of the book—is preceded by an excellent introductory account of the structure and classification of butterflies, and of mimicry and its relationship to other uses of form, colour, and pattern. The introduction is illustrated by the admirable first plate, showing the characters of the fore-feet of the principal butterfly groups. The discussion of special objections to the theories of mimicry, and a consideration of the evidence by which they are supported, are wisely left to the concluding pages of the text. A useful bibliographical list and an excellent index complete the work.

The extraordinarily rapid growth of knowledge on this subject at the present day is seen in the fact that important new light has been already thrown on certain conclusions in the few months that have elapsed since the appearance of the volume. Thus on p. 31 we read of the family raised by Mr. St. Aubyn Rogers from a female *Hypolimnas misippus* somewhat intermediate between the type and the form *inaria*, and of how the females, without exception, turned out to be *inaria*. But since the day of publication Mr. Rogers has bred in the same locality, Rabai, near Mombasa, another family from an *inaria* female parent, and in this instance all the female offspring were *misippus*! It should be mentioned in connection with this hitherto unpublished result that *misippus* and *inaria* females are about equally common in the locality where the families were reared.

Again, when the book was published it was safe to assert (on p. 96) that the *planemoides* female form of *Papilio dardanus* is restricted to the areas where its *Planema* models are abundant; but Mr. Rogers has now sent an example of it from the neighbourhood of Rabai, and Mr. G. F. Leigh an evidently closely allied very rare form from Durban, the former much to the east, the latter immensely to the south of any locality from which the models have been recorded.

Then the comparatively few African examples of mimicry within the Nymphalinæ have been increased by the recent observations of Mr. W. A. Lamborn that *Diestogyna gambiae*, the female of which resembles the abundant *Catuna angustata*, is constantly to be found in the company of this species.

Our knowledge of mimicry in Africa is progressing at a very rapid rate. To name only the principal naturalists who are directing their attention to this subject at the present moment, we have Mr. A. D. Millar and Mr. G. F. Leigh in Natal, Mr. C. F. M. Swynnerton in south-east Rhodesia, Mr. St. Aubyn Rogers in the Mombasa district, Mr. C. A. Wiggins at Entebbe, and Mr. W. A. Lamborn in the Lagos district. The present writer has found it most inspiring to be associated with all these keen observers and to receive many times in each year the tidings of new discoveries and the material on which they were based.

Mr. Eltringham's work will be of the utmost assistance to these and other naturalists, and it is to be hoped that it will be available in every African centre accessible to students of nature.

It will also be clear from the brief account of the plan and contents of the work that it is certain to be quite as valuable and efficient in stimulating and guiding the beginner as in aiding the expert in the search for fresh discoveries.

A careful and critical study has revealed comparatively few mistakes. All that have been detected are mentioned below, and in a book so full of statements of fact, the list must be regarded as a short one.

In mentioning *Cethosia* (p. 39, n. 2), the Oriental mimic of *Danaida*, it would have been well to point out that we here meet with one of the very rare instances of mimicry in the male, but not in the female. The mimicry is confined to the upper surface, and can hardly be looked upon as "remarkably accurate" in any species of this genus.

The male of *Planema macarista* should have been mentioned on p. 45 as a model of the *aurivillii* form of female of *Acraea alciope*. In both shape of wings and pattern the resemblance to this *Planema* is closer than to *P. poggei*, the model given by the author—a conclusion very clearly expressed in the arrangement of plate viii., but inadvertently omitted from the text.

In discussing, on p. 52, the scanty and somewhat imperfect mimicry of the abundant Danaine, *Tirumala petiverana*, the author omits the important consideration that the species is a *recent* intruder from another area—an intruder still retaining a close resemblance to its nearest Oriental allies.

In speaking, on p. 58, of the "black and white" varieties of *Pseudacraea lucretia* approaching the Danaine model *Amauris echeria*, the author is evidently referring to the individuals in which the normal white markings are to a greater or less extent replaced by ochreous.

It would have been appropriate to place *Acraea esebria* among the mimics of *Planema aganice* and its form *montana* (pp. 73–5). Furthermore, *aganice* is not "confined to the Natal region," but occurs in south-east Rhodesia and probably much farther north along the east coast. *A. esebria*, too, is not only southern (p. 81), but eastern in distribution.

Entebbe is given as the only locality of *Pseudacraea hobleyi* on p. 78, but its female, originally described as *tirikensis*, was first collected by Mr. C. A. Wiggins in a more eastern part of the circumference of the Victoria Nyanza, viz., Tiriki and Nyangori. It has been also received from Toro.

The Pterothysanid moth *Hibrildes neavei* is not "bisexually mimetic, and corresponds to the two sexes of *Acraea anemosa*" (p. 103). The mimetic *Hibrildes* is only known as a female, which probably belongs to one of the previously known non-mimetic males.

The admirable account of the most wonderful mimic in the world, *Papilio dardanus*, is accompanied by plate x, entirely devoted to the forms of this species and the allied *P. meriones* of Madagascar. The part of the preliminary list on p. 92 would have been better, from the point of view of evolution, as well as that of geographical distribution, in the order *polytrophus*, *dardanus*, *tibullus*, *cenea*. A more serious error in the same part of the list is the inclusion of the female forms *dorippoides* and *trimeni* in the sub-species *cenea*, instead of *tibullus*, although both are correctly placed in the full account on p. 100. The male of *dardanus* is inadvertently described as black and white on pp. 93–4, although its "pale yellow ground-colour" is correctly spoken of on p. 97. The males of *tibullus* (East Africa) are characterised by the strong development of the black submarginal band in the hind wing. Those of *cenea* (South Africa) differ in the smaller development of this feature. It increases rapidly as we pass northward, the *cenea* males being transitional into those of *tibullus*. The account on p. 100 conveys a nearly opposite impression.

The classification of so complex a subject as mimicry, under the limitations imposed by the ordinary printed page, must always be a matter of great difficulty. In some respects the author has not grappled with it very successfully. Thus his admirable account of the mimics of *Danaida chrysippus* does not seem to be very happily arranged. The species follow the order of the following column, the members of no single family or sub-family being all together:—

1. *Hypolimnas misippus*: Nymphalinæ.
2. *Pseudacraea poggei*: ,,
5. *Acraea encedon*: Acræinæ.
8. *Mimacraea marshalli*: Lycænidæ.
4. *Argynnis hyperbius*: Nymphalinæ.
7. *Acraea mima*: Acræinæ.
6. *Acraea wigginsi*: ,,
9. *Cooksonia trimeni*: Lycænidæ.
3. *Diestogyna iris*: Nymphalinæ.

In spite of this dislocation of the groups in the text, we find that all four Nymphalinæ are near together on plate ii, while the three Acræinæ and the two Lycænidæ are also together on plate iii. The most obvious sequence on the plates is that indicated by the numbers to the left of the column, a sequence far better than that adopted in the text. It is, in fact, the best possible arrangement, except for the position of *Argynnis hyperbius*, which, being restricted in Africa to Abyssinia, is best placed at the head of the list—as far as possible from all the rest. It would then be followed by the wide-ranging *H. misippus*, the only Nymphaline mimic with which it is associated. The remaining seven species, together with *H. misippus*, form a very natural group, some of them wide-ranging, the others, except the more equatorial *A. wigginsi*, especially characteristic of northern Rhodesia.

Having in view the needs of naturalists who are beginning the study of mimicry in butterflies, and we hope that large numbers of them will seek the valuable and important help offered in this beautiful work, it would have been advantageous to make the group-names a prominent feature in the descriptions of the plates, and also to print comprehensive descriptive titles beneath the plates themselves and above the descriptions of each. Thus plate ii. might have been briefly explained as "*Danaida chrysippus* and its Nymphaline Mimics." The arrangement of models and mimics in separate columns in the description of the plates is an admirable feature, as also is the printing of the names of the species beneath the figures on the plates themselves.

The succession of the models in the text might also, we think, be improved. Thus the deeply interesting series of Planemas with *Pseudacraea* mimics, begun on p. 65, is interrupted (pp. 66–9) by the great black-and-red combination ranged round *Acraea egina*, and by the purely Nymphaline association of *Crenis* and *Crenidomimas* (p. 70), and then again resumed on pp. 70, 71, *et seq.*

The author has wisely preceded his account of mimicry by a classification, on pp. 11, 12, of the chief butterfly groups, with a few of the main features by which each is distinguished. Such a classification will be of great value to those who are beginning the study of mimicry in the field, and have not the means of referring to the literature of the subject. It is a pity, however, that the Brassolinæ and Morphinæ are separated from their close allies, the Satyrinæ, by the intercalation of the Acræinæ and Heliconinæ—these latter being themselves similarly cut off from the Nymphalinæ, to which they bear so close an affinity. The author is here following in the main the key given by Mr. Roland Trimen in his South African Butterflies; but in this great work a linear arrangement based on affinity is printed on the opposite page, and is adopted throughout the volumes.

It is also unfortunate that the division of the "Heliconidæ" of Bates into Ithomiinæ and Heliconinæ is recognised neither in the classification nor in Mr. Eltringham's further discussion of the groups on pp. 17, 18. The composite nature of the "Heli-

conidæ" was fully accepted and explained by Bates in his paper on mimicry, where he speaks of the "Danaoid" and the "Acræoid" Heliconidæ. And since Bates's time the strong difference on which he insisted has been further emphasised by creating a separate Nymphalid sub-family, the Ithomiinæ or Neotropinæ, for the larger group, the "Danaoid Heliconidæ." *Ituna* and *Thyridia* are mentioned on p. 18 as belonging to the Danainæ; but the latter genus is Ithomiine, as Fritz Müller proved in 1879; and the author's argument in favour of mimetic approach is much strengthened by the great width of the interval between it and *Ituna*. The omissions and errors in this and the last paragraph are, however, concerned with tropical American butterflies, and do not greatly affect the value of a work on African Rhopalocera.

The author's arguments are clear and convincing, and he handles his intricate subject with great skill. The following line of reasoning is, however, open to criticism.

Speaking of the female of the Oriental *Argynnis hyperbius*, which, over nearly the whole area of its distribution, mimics *D. chrysippus*, but in Australia resembles its own male, and is non-mimetic, the author concludes:

"Since it has become established in Australia before the advent of the Danaine, mimicry of the latter is unnecessary for its continuance."

We are not convinced that this reasoning is sound. It may well be that the representative of *D. chrysippus* has not existed in Australia for a sufficient length of time for the mimicry to have originated; but the above argument seems to imply that a well-established indigenous form would never be influenced by an invading model. There is good evidence that such a change is ultimately wrought, as we see in the effect of the Old World Danaidas upon the North American *Limenitis* (*Basilarchia*), and of the Oriental Tirumalas (*Melinda*) upon the Ethiopian Papilios, so beautifully illustrated by Mr. Eltringham on plate iv of the present work. If these Danaines had not invaded the areas of which we speak, there is little doubt that the species of *Limenitis* and *Papilio* would be still living, but of course without their present mimetic patterns. A certain average proportion of destruction takes place in every generation. The advent of a dominant Danaine model does not necessarily alter this proportion numerically, but affects its quality. Whereas variations in the direction of the model were previously distributed at random among the eliminated and the survivors, they now tend, in each generation, to be more thinly scattered in the former set, more thickly in the latter. And the same conclusion holds for every step by which an elaborate likeness is finally produced.

The above considerations doubtless supply at least in part an interpretation of polymorphism in mimicry—the fact that a single mimicking species often appears in two or more quite different forms resembling different models. For when—by the spread of either itself or the mimic—a new and dominant model, A, comes into relationship with the mimic of an older model, B, the same conclusion holds. The eliminated proportion of the mimic will now for the first time tend to contain less, the surviving proportior more, of any variation in the direction of A, and afte a time the mimic may resemble both A and B. Often, but by no means always, such a process is transitional affording the means by which the mimic finally come to resemble A in one part of its range, and B i another. A good example is to be found in the femal of *Acraea alciope*—a tangled problem most skilfull unravelled by Mr. Eltringham not many months ago The usual western female of this species mimics th common pattern of the western male Planemas Further east, at Entebbe, this pattern, although i occurs, is by no means dominant, and the ordinar form of female *alciope* mimics the male of *Planem macarista*, and both sexes of *P. poggei*. But rar examples of the western mimic are still to be foun among the *alciope* females at Entebbe, and of th eastern mimic on certain parts of the west coast The probability that the younger mimetic pattern almost certainly the eastern—has been reached throug dimorphism, is extremely strong.

The author alludes to this deeply interesting subje of polymorphism in mimicry—shown by the recen researches of Dr. Karl Jordan to cover a far wide area than has been hitherto supposed—and infers o pp. 62, 63 that the only interpretation is to be found i Bates's hypothesis of a palatable mimic resemblin a distasteful model:

"We are forced . . . to the conclusion that specie which in the same locality produce polymorphi mimetic forms are Batesian mimics, and that the valu of the multiple varieties lies in the distribution of th mimetic forms amongst a corresponding number o models, thus avoiding the risk of the edible mimi becoming more numerous than its distasteful mod a state of things which would lead to a disastrou increase in the amount of experimental tasting b insectivorous animals."

In other parts of his work the author himself compel us to doubt the cogency of this reasoning, for h figures and describes such polymorphic mimics amon the highly distasteful Acræas—for instance, *A. jodutt* with its two forms of female at Entebbe, and th wonderful series of mimetic patterns exhibited b *A. johnstoni* in British and German East Africa.

There are a few typographical errors, such a "survivials" on p. 23, which we should scarcely hav expected in a book produced by the Oxford Universit Press, and should also have anticipated that its exce lent readers would have directed the attention of th author to an awkward slip in the construction on l. from the bottom of p. 78, as also to a few "spl infinitives" scattered through the pages.

The abundant names of species and genera ha been very accurately printed. We notice only a sing error—*Pseudobazis* for *Pseudohazis*, on p. 118. Amo names of persons *Guillème* is printed for *Guillemé*.

Mr. Eltringham's monograph is the first attem to set forth a nearly full account of mimicry in t butterflies of one of the great tropical regions. has very wisely selected Africa for his purpose. examples are far more numerous and perfect th those of the Oriental region; yet they are manageal

and not bewilderingly complicated like those of tropical America. Africa, too, is especially rich in naturalists who are waiting to be inspired and encouraged, as they will assuredly be by the present work. The author is to be congratulated upon the fine volume and the beautiful plates which are the outcome of his labour of love. It cannot be long before he may be congratulated upon their fruitful results. E. B. P.

THE GEOLOGY OF EGYPT.

Geological Map of Egypt. Scale 1 : 1,000,000 (six sheets) and reduction of the same to the scale 1 : 2,000,000. (Cairo: Survey Department, 1910.)

SOON after the occupation of Egypt by a British military force in 1882, the late Prof. Huxley, then president of the Royal Society, directed attention to the valuable opportunity that was afforded for the extension of our geological knowledge in that interesting country. He instanced the valuable series of scientific memoirs that had been prepared by French savants during the occupation of the country at the beginning of the nineteenth century, as an example worthy to be followed. Following his advice, the Royal Society appointed a "Delta Committee" to arrange for explorations, which it seemed desirable to undertake, and made various grants from its funds to defray expenses. The War Department of the Government, on being applied to by the Royal Society, agreed to lend the service of some of the engineer-officers, then in the country, to supervise the work.

As the result of these arrangements, borings were put down at a number of points in the Nile Delta, and reports on the materials sent home were submitted to the society by the Delta Committee in 1885 and 1897, and were published in the Royal Society Proceedings.

But in 1893–4 an engineer-officer, Captain H. G. Lyons, already known in this country by his geological work in the Bagshot area, was employed on patrol work in the oases of Kharga and Dakhla and in the desert routes to the south of them, and he took the opportunity thus afforded to him for making a number of geological observations in the district, which proved to be of great value and interest. Two years later the Egyptian Government decided to establish a geological survey of the country, and to place it under the direction of Captain Lyons. A staff of surveyors was formed, consisting of four young geologists from the Royal College of Science—Messrs. Barron, Beadnell, Hume, and Ball—and for a time Dr. Blankenhorn acted as palæontologist to the survey. The first named of these surveyors, after doing much excellent work, fell a victim to the climate of the Sudan in 1906. A number of very valuable memoirs by Captain Lyons and his staff have been published, some of which have been already reviewed in the pages of NATURE.

As Egypt and the Sudan have no good topographical maps to be placed at the disposal of the geological staff, topographers have had to be attached to each of the geological surveying parties; in this branch of the work Mr. F. W. Green, of Cambridge, a good archæologist, has often served as a volunteer. In 1898 Captain Lyons took over the charge of the whole of the survey departments of Egypt, while continuing his direction of the geological work.

It is not possible here to enumerate all the advances made in our knowledge through the labours of the little staff of geological surveyors in Egypt, but especial mention may be made of the important palæontological discoveries of Mr. Beadnell, aided by Dr. Andrews, in the Fayum, which included the finding of the wonderful Arsinotherium, and the ancestral forms of elephants and whales. Scarcely less interesting and important are the results obtained by Dr. Hume in his surveys of the Sinaitic peninsula, and of the eastern and south-eastern deserts of Egypt; and by Dr. Bell in his work around several of the oases and cataracts.

The results of all these researches are incorporated in the new geological maps of Egypt now issued. In spite of the existence of considerable blanks, these maps are a very great advance on any that have hitherto appeared. The oldest fossiliferous formation recognised is the Carboniferous, but considerable areas have to be mapped as "Nubian sandstones," portions of which may be of different geological age; there are also beds of gypsum, the position of which in the geological series is in some cases still doubtful. The Cretaceous strata are divided into Cenomanian, Senonian, and Danian, while the extensively developed Eocene strata have been distributed in three local divisions. Strata referred to the Miocene and Pliocene also occur, while Pleistocene and more recent deposits obscure wide areas. The larger-scale map forms six sheets, and the smaller a single sheet; all these are admirably printed in colour, and corresponding maps with hill-shading have also been issued by the Survey Department.

The survey staff has lost its original director, Captain Lyons, and also Mr. Beadnell, but it has been reinforced by the appointment of Mr. H. T. Ferrar, the geologist of Captain Scott's first Antarctic expedition; there have also been several other geologists who have served temporarily on the staff. The work is carried on at the present time under the directorship of Dr. W. Fraser Hume, who has had such a wide experience in desert-work, and is responsible for the maps which form the subject of the present notice. We are glad to learn from the last issued report of the survey that Dr. Hume proposes to write a general sketch of the "Geology of Egypt," this work, from such capable hands, will be looked forward to by geologists with much interest.

J. W. J.

THE BEGINNINGS OF BOTANY.

Landmarks of Botanical History. A Study in Certain Epochs in the Development of the Science of Botany. Part i., Prior to 1562 A.D. By E. L. Greene. Pp. 329. (City of Washington: Smithsonian Institution, 1909; Smithsonian Miscellaneous Collection, part of vol. xliv.)

DR. GREENE has contributed to the history of the progress of botany a work that bears evidence of unwearied research into the labours of

botanists whose influence on the science is realised by few, and whom it is well to remember with respect and gratitude. The book is wholly devoted to the early beginnings of the knowledge of plants, and to the revival of their study in the fifteenth and sixteenth centuries. It is not a work to be taken up to pass a leisure half hour. One feels disposed at times to question the author's presentation of his subject, but when the book has been read through one feels that it has well repaid the effort in the suggestive lights it has thrown on the past, on problems that are still with us, as well as on others that are no longer problems because solved for us by those early botanists. The treatment of the subject makes this book a valuable complement to the well-known "History of Botany" by Prof. Sachs, and there is much additional information in it.

Dr. Greene frequently is drawn into philosophical discussions in the definitions of his subjects. He defines the science of botany for the present work as occupied with the contemplation of plant as related to plant, and with the whole vegetable kingdom as viewed philosophically—not economically or commercially—in its relation to the mineral on one hand and to the animal on the other. From this point of view he recognises the beginnings of the science in the study of plants as plants, apart from their real or supposed economic worth. He finds true botanical science in the natural groups of popular language, and even in such terms as "herbs," "trees," and "grass," and still more clearly in such as "clover," "oak," &c. The correlation in value or kind of these and the like with the "genera" of systematic classification is insisted on. He concludes his introduction with impressing the view that "the essence and substance of botany proper are organography and the logical deductions we may draw from organography. The line of development of organography—as including terminology—is that along which a truly coherent and philosophic account of botany must be written."

A brief chapter is devoted to the Rhizotomi, whose maxims—so readily condemned as superstitions—he gives reasons to regard as in many cases judicious and well-founded.

By far the greater part of the book is occupied with brief biographies and detailed consideration of the work of five writers: Theophrastus of Eresus, Otto Brunfels, Leonhard Fuchs, Hieronymus Bock (Tragus), and Valerius Cordus. Short chapters on Greek and Roman writers after Theophrastus, on the early German writers, and on Euricius Cordus, father of Valerius, complete the volume.

Few botanists can claim to have gained a knowledge from his own writings of the part filled by Theophrastus in the progress of botany. To most Dr. Greene's estimate of his work will prove a revelation of a very surprising kind. The minute and careful analysis of the information contained in the two books that have survived, in an unfortunately imperfect state, shows that he was a genius and investigator far in advance of other botanists of his time. A recapitulation is given at the close of the chapter indicating seventeen heads regarded as "elements of universal botany of which Theophrastus appears to have been the discoverer and first promulgator." While it may be felt in regard to some of these that Dr. Greene is disposed to press the point unduly, the larger part are of such importance as to justify the claim to a front rank among botanists, and to show the inadequacy of the judgment expressed on him in Sachs' book.

Brief notices of Dioscorides, Varro, Virgil, Pliny, Galen, and others, bring out the contrast of these with Theophrastus, their inspiration being chiefly the study of plants for their useful or harmful properties, though they also added at times to the knowledge of plants as plants. During the long period of more than twelve centuries after the time of Galen, the natural sciences, instead of advancing, fell much into decay, and were in part represented by such works as the "Ortus Sanitatis," filled with grotesque figures and strange perversions of the truth.

The reawakening from this condition is placed by German historians of the science, such as Meyer and Sachs, in the sixteenth century, when the "Herbarum Vivæ Iconoes," of Otto Brunfels, was issued, and was succeeded by, among others, the works of Fuchs, Tragus, and Valerius Cordus. Brunfels and Fuchs, he points out, busied themselves almost wholly with plants as medicinally valuable; and their books are little more than compilations illustrated by figures of the plants to which they believed their borrowed descriptions referred. These figures were excellent in comparison with those in use previous to Brunfels, but in other respects neither Brunfels nor Fuchs can be shown to have made any important step forward. Fuchs introduced his "Historia Stirpium" with "An Explanation of Difficult Terms," from which his views on the structure of plants can be gathered, and are found in general to be retrograde from those expressed by Theophrastus.

Bock or Tragus (1498–1554) had a different point of view from Brunfels and Fuchs, and may deservedly be accepted as having opened the new era of botany. He studied plants for their own sakes; and, possibly in part from inability through poverty to employ illustrations in his "New Krauterbuch," he sought to describe them so clearly as to make it possible for others to recognise them from the descriptions alone. He wrote his books in German instead of the customary mediæval Latin; a translation into Latin being afterwards issued for use in other countries. He merely names the common and well-known plants, describing the scarcer and previously unknown forms. His method required, and was based on, very careful personal investigation; and he thus was able and was led to make important contributions to the science in various directions. Dr. Greene discusses Tragus' views on classification, nomenclature, ecology, &c., very suggestively and justly, with full recognition of his great merits but also calling attention to errors.

Euricius Cordus is given a place of honour for his sole botanical work, in which he points to defects in the study of botany in his day, but still more as the father and teacher of Valerius Cordus. The latter died at the age of twenty-nine, while travelling in Italy, but had won reputation by a work on the preparation of medicines published during his lifetime

He had travelled extensively in remote parts of Germany, had discovered many more plants than had been made known since the revival of botanical study in Germany, and had described these carefully in a work, "Historia Plantarum," left in manuscript. This was published some years after his death, edited by Conrad Gasner, who, by desire of the publisher, employed illustrations (prepared to accompany Tragus's work) to illustrate the descriptions of Cordus, to which they were occasionally incorrectly fitted. From a careful study of the descriptions, Dr. Greene shows cause to regard Valerius Cordus as of rare ability and insight, and esteems him to have been immeasurably the greatest of the "German fathers of botany." Among the services to botany ascribed to him we are told that "he is the inventor of the art of phytography"; that in all descriptions "attention is given to the morphology and life-history of the plant in as far as is known to him"; that new terms are employed expressing new ideas and points of view in the science, and that new conceptions appear in regard to inflorescences, flowers, fruits, and seeds. In taxonomy he shows clearer views with regard to species, and his groups were more often based on relationships than were those of his predecessors. A number of his groups of generic rank stand good, though in most cases the names given by him were needlessly changed by Linnæus. He paid heed to internal structure (so far as that could be determined by him, that is, by the unaided eye), and to physiology, as regards prefloration, modes of climbing, and similar features of plant-life. He also gave attention to the varieties of cultivated fruits, of which excellent descriptions are extant by him. What he succeeded in doing suffices to show how grievous a loss botany sustained in his early death.

VECTOR ANALYSIS.

Éléments de Calcul vectoriel, avec de nombreuses Applications à la Géométrie, à la Mécanique, et à la Physique mathématique. By Prof. C. Burali-Forti and Prof. R. Marcolongo. Édition française traduite de l'Italien et augmentée d'un Supplément par S. Lattès. Pp. vi+229. (Paris: A. Hermann et Fils, 1910.) Price 8 francs.

THE variety of matter contained in this small book shows the condensing power of vector notation, especially when combined with a concise literary style. The theoretical part includes the elements of the barycentric calculus, as well as a vector analysis in which vectors are written either in single letters, or in the form B–A, where A, B are points. Scalar and vector products are treated separately, so that quaternions do not come in. Special points to notice are that a scalar product has given to it the sign opposite to that assigned by Hamilton; the effect of this is that if α, β, γ are three orthogonal unit-vectors, $\alpha^2=\beta^2=\gamma^2=1$, and versors have to be treated by introducing a symbol i, such that $i^2=-1$, and is *not* a vector. There is a good deal to be said for this; but it is most unfortunate that the authors take the clockwise sense of rotation for the positive one, especially considering the use of vectors and vector products in physics.

The applications include geometrical, mechanical, hydrodynamical and electrical formulæ. Specially to be noted are the proofs of Green's theorem and its congeners, Stokes's theorem of circulation, and Hertz's formula for variation of flux.

There is an appendix, partly historical, partly critical and even polemic. Probably every reader will find something here with which he cordially disagrees; but there is one statement that deserves special attention. We believe that the authors are right in thinking that the final notation of the vector calculus will be based on Grassmann's "Ausdehnungslehre," as improved and modified by subsequent writers. The Hamiltonians will have nothing more than a sentimental grievance if this proves to be the case. Nothing can upset, or even modify, the quaternion calculus, because it is a definite type of linear algebra; the main question now is whether *this* algebra is the best for the treatment of physical, and especially electrical, problems. Judging by the attitude of Gibbs, Heaviside, and Lorenz (to name only these), the answer appears to be no.

There is very little fear that a really convenient notation will not be ultimately agreed upon; it will probably be invented by a physicist. Meanwhile, dispassionate observers will derive some amusement, as well as much instruction, from the lively controversies of the champions of this or that particular symbol, as if its retention or rejection were of vital importance in itself. For instance, our authors seriously object to a symbol such as $[\alpha\beta]$ for a scalar product, on the ground that functional symbols are invariably placed on one side of the operand! The example of $\int y dx$, where $\int () dx$ is practically a functional symbol, shows that the statement is barely true, except in an artificial sense; but even if it were strictly true, this would be no reason for regarding it as a necessary law of mathematical notation.

G. B. M.

MAP-MAKING.

The Theory of Map-Projections, with special reference to the Projections used in the Survey Department. By J. I. Craig. Pp. iv+80. (Cairo: National Printing Department, 1910; Ministry of Finance, Egypt Survey Department.) Price 200 milliemes.

THE subject of map projections is one in which the English language is strangely deficient, a deficiency the more apparent when contrasted with the wealth of Continental literature on the subject. Those interested in the higher theory of map-making will, therefore, welcome the appearance of this little treatise, which seems to give in a compact and practical shape all the essentials of this attractive branch of the geometry of surfaces. Starting with a statement of the problem to be solved, and an allusion to possible improvements in nomenclature; the term projection itself, in the meaning of a representation in accordance with any law, for instance, is not a particularly happy one; a history is given of the adop-

tion of the Gauss conformal meridional projection for the maps of the survey of Egypt. A general discussion of the figure of the earth, and the geometry of the surface of a spheroid, is then entered upon, leading the way to the theory of the representation of such a surface on a plane sheet and the involved balancing of errors. These general results are then applied to the standard projections, so that, while special attention is devoted to the Egyptian mapping, the major part of the book is of quite general application. The methods of investigation are, in many cases, new, and the mathematical forms concise and elegant.

As an interesting example of specialisation, we may note the investigation, on p. 61, of the Mecca retro-azimuthal projection, which would provide a map giving the true bearing of Mecca at any point.

The great variety of projections used for the maps of different countries gives rise to certain inconveniences, and it is an arguable point whether it would not be possible and desirable to reduce this number to a few standard forms by international agreement. What has already been accomplished in the case of the 1/1,000,000 map of the world might be extended to apply to other scales. We commend the subject to the attention of the next International Geographical Conference. It must always be bōrne in mind that while the selection of a suitable projection is important for atlas or general maps upon small scales, it is comparatively unimportant for large-scale survey maps produced in sheets, so long as each sheet is projected separately. The errors due to defects in the projection are always small compared with those due to the distortion of the paper upon which the map is drawn or printed.

E. H. H.

OVERHEAD AND UNDERGROUND ELECTRIC LINES.

Lignes Électriques Souterraines. Études, pose, essais, et recherches de defauts. Pp. 207.

Lignes Electriques Aériennes et Souterraines. Études, pose et essais. Pp. 181. By C. Giradet and W. Dubi. (Grenoble: J. Rey; Paris: Gauthier-Villars, 1910.) Price 5 francs each.

THE superscription on each of these volumes: "Bibliotheque de l'eleve-ingenieur," seems to indicate that they are written by and for graduates of engineering colleges, and this impression is confirmed by an introduction contributed by Prof. J. Pionchon, of the Dijon University, in which we are told that the "library" is intended to form a kind of post-graduate instruction to engineering students. To expect students shortly after they have graduated to be able to become authors on technical subjects and write books, which shall be good enough to serve as further instruction to other students which may graduate a year or two later, is hardly reasonable; but in the present case the difficulty is partly overcome by the circumstance that one of the authors is not a student fresh from college, but evidently a man of considerable practical experience in overhead power-lines and cable work.

Yet the result of the collaboration is rather disappointing. The books are neither scientific—in the sense of showing the connection between engineering practice and scientific principles—nor are they very practical in the sense of containing definite instructions. There is a little of each, and a good deal of what may be described as general talk on the subject, and containing little which is not self-evident to a man of average intelligence. Thus, when the authors tell us that overhead power-lines should be so constructed that copper may be added as the demand for power increases, everybody will agree, but is it necessary to labour so obvious a matter? On the other hand, some of the general talk is misleading. Take the statement that cables for very high pressure have no practical importance, since cables are only used within towns, that is, over relatively short distances; or the recommendation to earth the middle wire in a three-wire system at every junction box. Then, again, we find ten pages of what may be called general talk about various junction boxes, but not a single drawing to illustrate the types discussed; whilst the important matter of mechanical protection of cables is dealt with on only two pages, and illustrated by two small scale sections, one showing bricks laid over the cable longways and the other showing them broadways.

The most elaborate technical part of the book on underground lines is that on localisation of faults, and here, by the preface, we are led to expect specially valuable information; for the authors say in it that although the methods given in "some text-books" are sufficiently well known, yet their practical application under the varying and difficult condition of actual service, demand special elaboration. This is certainly true, and one turns with eager expectation to the chapter in question in order to see what the authors have to say about these special devices. Here again we are rather disappointed; although the author who has contributed this part is certainly a man who knows his subject well, and gives a series of practical and numerical examples evidently culled from his practice, one does not find much which may be considered as new methods. Our old friend the loop test crops up in various guises, and when we are told that a special wire must be run where no sound cable is available to complete the loop, the advice is, no doubt, quite serviceable, but it can hardly be considered as an advance upon the text-book method; it is simply an obvious way of carrying it out.

For the localisation of a break in the conductor a method based upon measurement of capacity is recommended. This also is old. Most engineers will expect that when a cable parts bodily the insulation at the break will also be destroyed, so that a method based on the measurement of capacity becomes inapplicable; but, curiously enough, the authors give a case from their experience where the insulation had remained perfect. The history of this breakdown, and of the expedients employed to keep the service up under a variety of great difficulties, is very interesting reading, whilst the fact that the engineers were able to locate the break within a few yards is a striking vindication of a method which at first sight seems of doubtful value. What the authors have to say about the legal

aspect of overhead lines applies to France only; but their remarks on wayleave, compensation to landowners, organisation of working parties, establishment of work-places for the manufacture of ferro-concrete masts at various parts of the line, the transport of these masts, their erection, and other matters of an administrative nature, is well worth reading, and is, with but slight modifications, also applicable to similar work when done in this country.

GISBERT KAPP.

OUR BOOK SHELF.

Facts and Fallacies regarding the Bible. By W. Woods Smyth. Pp. x+208. (London: Elliot Stock, 1911.) Price 3*s.* 6*d.* net.

MR. WOODS SMYTH aims at showing that modern scientific knowledge is in agreement with Divine revelation as recorded in the Bible. He considers that the Mosaic account of the creation of worlds and of the various forms of life up to man should be accepted as an authoritative and accurate statement of inorganic and organic evolution. "The sober truth is," he says, "that wherever the Bible touches upon questions of science it does so with a grace, an accuracy, and a philosophic perfection which surpasses every text-book of science in existence."

This position is clear enough, and we cannot but admire the author for his courage in occupying it in spite of the difficulties involved. We believe, however, that he will not find supporters among theologians who know most of the origin of the Scriptures or among philosophers who are best acquainted with the facts of nature. If all scientific knowledge and theory of to-day can be shown to be only a confirmation of the Biblical record, what will be said a hundred years hence, and what was the case in the time of early Greek philosophers? Science is progressive, and the accepted views of one generation become the discarded lumber of another.

Unless, therefore, the Bible is regarded as containing all scientific knowledge for all time, there is not much purpose in showing that science and revelation are in agreement at a particular epoch, even assuming this to be the case. A more reasonable view to take is that the Scriptures are faithful historical records of what was thought or believed when they were compiled, containing observations of obvious phenomena only, and interpretations appropriate to the period in which they were made. Any attempt to show that the facts of modern science can be confirmed by reference to an inspired literature must depend upon special pleading for its case, and can do little to further the desire "to restore the Bible to its high place of authority by restoring faith in the subject-matter of the Divine revelation."

"I Wonder" Essays for the Young People. By the writer of "Confessio Medici." Pp. 109. (London: Macmillan and Co., Ltd., 1911.) Price 3*s.* 6*d.* net.

THE young people to whom the author refers on the title-page of this book must be of a metaphysical frame of mind to be able to read these essays with interest and intelligence. The subtle reasoning occasionally involved requires careful thought for its comprehension, and is best appreciated by the adult philosopher. A fine distinction on the use of the verb "to wonder" is made in the first essay. "Make up your mind," says the author, "that you will only wonder at," and do not wonder if, is, when, or where. But the verb signifies to doubt or expect as well as to marvel; so that the advice given need not be taken literally. There is a useful lesson in the second essay, which aims at showing that many attributes of things exist only so far as our senses are able to appreciate them; but it will be lost on most young people. Other essays deal with the wonder of nature, of self, of pain, of death, of beauty, and the use of wonder.

It is scarcely correct to say that "there are gases to which the air is as paving-stones to feathers," or that the something—signifying the ether—which exists throughout space "is one and the same energy, manifest in all things." If, as the author says, "it takes a fellow of the Royal Society to think of the interstellar ether," it may be said with equal approach to accuracy that membership of the Aristotelian Society is desirable to appreciate the points of some of his essays. The book has, however, the merit of fine style and noble thought, and provides an admirable antidote to the influence of overmuch attention to materialistic affairs.

Das biologische Schullaboratorium. By Dr. W. Schoenichen. Pp. 67. (Leipzig: Quelle and Meyer, 1910.) Price 1.60 marks.

IN this pamphlet Dr. Schoenichen gives an interesting account of the structural arrangements, equipment, and course of study in the biological department at the Helmholtz "Realgymnasium" in Schöneberg. The author passes rather lightly by the courses of general zoology and botany, though there is abundant internal evidence that these subjects are accorded a generous and judicious treatment. His main purpose appears rather to be to lay stress upon the hygienic value of biological study as a subject of general education. In this country a certain hazy conception of spores, germs, bacilli, bacteria percolates through the medium of the daily Press into the mind of the man in the street, but neither he nor his wife has any real knowledge of the "why" and the "how" of personal or domestic hygiene. About half of the present treatise is more or less directly concerned with this aspect of biology, and accordingly we find full accounts of a few of the more common species of moulds, of nutrient media, and the various appliances employed in connection with them; of the process of sterilisation and the production of "pure" cultures. A prominent place and full description are given of Prof. Lindner's ingenious "roll-cylinders," and of their employment in the biological analysis of air, water, &c., and his method of "drop-culture" is well explained and illustrated.

The concluding pages are devoted to a brief survey of the biological courses at ten of the German universities.

What will the Weather Be? The Amateur Forecaster's Vade Mecum. By H. G. Busk. Pp. 27. (Cambridge: W. Heffer and Sons, Ltd.; London: Simpkin, Marshall and Co., Ltd., 1911.) Price 6*d.* net.

THIS little manual is intended to enable the non-scientific reader to forecast the weather, for a day in advance, from his own observations. Tables arranged under the principal wind directions show the average conditions of weather to be expected in winter and summer, with changes of barometrical pressure. The work is accompanied by a useful introduction by Mr. H. B. Stone, explaining the usual sequence of weather in areas of high and low atmospherical pressure; it is this principle that lies behind the tables, and may enable a forecaster to obtain "reasonable accuracy" by their use. More accurate forecasting depends upon the tracks actually being taken by cyclonic disturbances and other considerations, including the configuration of the ground.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Non-simultaneity and the generally Eastward Progression of Sudden Magnetic Storms.

UNDER the above heading, Dr. L. A. Bauer contributes to NATURE of March 2 a letter of five columns. Referring to his Table II., p. 10, he says:—"It will be noticed that Kew is not included, for the simple reason that although Dr. Chree scaled the required data some months ago, he has not yet published them nor forwarded them to me"; and later he adds:—"Dr. Chree could not have done better than immediately to have published his own data in the same open manner that Mr. Faris had done. Instead, he labours to discredit the Coast and Geodetic Survey observations, and withholds his own from public scrutiny. In half the interval of time between the first and second presentation of his paper, had Dr. Chree chosen, he could have had at his command data from Europe and Asia which, combined with his own, would have served admirably to have tested the main contentions." The real facts are as follows. In July, 1910, I consulted the Kew curves for the dates of the fifteen disturbances treated by Mr. Faris and Dr. Bauer, and, as stated in the paper read before the Physical Society (Proc., vol. xxiii., part i.) on November 11, "I was able to identify ten of the fifteen disturbances with reasonable certainty." The measurements I then took were confined to the times of commencement of these ten disturbances. Dr. Bauer's request for data, which reached me in January, included, not merely the times, but the amplitudes of all the movements. I supposed, mistakenly, as it proves, that before publishing anything Dr. Bauer would await the data from the more remote stations, which could not well reach him in less than two or three months. I thus gave precedence to official work of urgency. Also, to get the best results possible, I had an independent set of measurements made by my chief assistant, and took a fresh set myself, and considered carefully all cases in which the times obtained differed by more than one minute, the limit of accuracy I hoped to attain. In a good many cases I was doubtful which of several small movements was the one intended, so curves were drawn indicating the movements and times, and amplitudes were given for the various alternatives. The results of this very considerable labour were dispatched to Dr. Bauer on February 25, no hint having meantime been received from him that the data were urgently wanted.

The charge that I laboured to discredit the Geodetic Survey observations is equally unjustifiable. As anyone who reads my paper will readily recognise, my criticisms were directed, not against the observational data—which, I may say, struck me as quite up to the usual standard of observations—but against the use made of them. In bringing forward these criticisms, I hoped to do better service than by collecting a number of other miscellaneous data, affected by similar uncertainties, the course which Dr. Bauer thinks it was my duty to adopt.

As Dr. Bauer takes no notice of my criticisms, I should like to indicate briefly their nature, to assist the comprehension of your readers.

Mr. Faris deduced times of commencement and corresponding velocities of propagation from Horizontal Force (H), Declination (D), and Vertical Force (V) curves separately. On the average, the H times preceded the D by 0·44 and the V by 2·3 *minutes*. I indicated the improbability of the disturbing force commencing with a component along one only of the three fundamental directions at a station. Normally, one must expect components in all three directions; thus systematic differences in the times of occurrence in the D, H, and V curves can hardly be real. To be visible, a disturbance must attain a certain amplitude. So-called "sudden commencements" really take several minutes, as a rule, to reach their maximum, and the apparent differences in time mean, presumably, differences in the amplitudes of the three components, or difference of sensitiveness in the three magnetographs. The neglect of this point of view may lead to serious error. To see this, take a simple case. Suppose a number of similar compasses to be placed on a straight line radiating out from an electromagnet. Suppose each needle frictionless, but its displacement imperceptible until it attains 1′. Let, now, a slowly increasing current actuate the electromagnet. As the current rises, movements become visible in one compass after another, and an unscientific observer might infer that a disturbance was being propagated outwards from the magnet with a velocity which might be very small if the current increased very slowly. The time, however, when any compass is visibly affected is determined, not by the velocity of propagation of electromagnetic waves, but by the sensitiveness of the needle, its orientation, and the rate of increase of the current actuating the electromagnet. Disturbances of the type selected by Mr. Faris are usually largest in H and least in V, and it thus appeared to me highly suggestive that the times derived from the H curves were so markedly the earlier. The tendency in all cases must be for the time shown to be late, the error being greater the smaller the disturbance and the less sensitive the magnet. If, then, on any given occasion, a disturbance nowhere large were smaller in Europe than America, we should expect the time of commencement shown by the average European magnetograph to be a little behind that shown by the average American instrument.

Another criticism I made was this. Originally—so far as I could understand—Dr. Bauer and Mr. Faris assumed differences in times at any two stations to depend only on differences of longitude. This implied that the disturbance travelled either due east or due west, appearing simultaneously at all places in the same longitude. Five American stations were arranged in two groups, the mean longitudes (79° 9′ W. and 146° 42′ W.) of these being regarded as belonging to two central stations 68° apart. Call these two imaginary stations A and B, the former being the nearer to Greenwich. It was recognised by Mr. Faris that a disturbance travelling, say, westwards, might pass A first, reaching B after travelling 68°, or it might pass B first, reaching A after a journey of 292°. In the former case it originated in the wide zone, 267°, separating the extreme stations Honolulu (158° W.) and Porto Rico (65° W.); in the latter case it originated in the narrow zone, 40°, separating Baldwin (95° W.) from Sitka (135° W.). The peculiarity I dwelt on was that no fewer than nine out of the fifteen disturbances were treated as if originating in the narrow zone, whereas one would have expected only two or three. Dr. Bauer does not refer to this point, but the method he now follows seems different. He again takes two central stations, this time one in America, the other in Europe, but he determines the velocity, apparently, not from the difference of longitude, but from the arc 75° on the connecting great circle. Further, he tacitly assumes that all the disturbances commence in the wide zone between the westmost American and eastmost European station, as all are assumed to traverse the 75° arc and none the 285° arc. This may or may not be a better plan than that first adopted, but it is totally different. A hypothesis which makes all the fifteen storms originate between Honolulu and Katharinenburg is obviously incompatible with one that makes nine out of the fifteen originate between Baldwin and Sitka.

Dr. Bauer's second method would avoid the difficulty I pointed out of supposing that the velocity near the poles is not merely moderate, but actually small. It has, however, this obvious drawback, that it cannot give a true velocity at all unless we suppose the disturbances to actually travel along one particular great circle connecting two arbitrary points on the earth's surface.

One of my criticisms related to inconsistencies between the times shown by different stations and the conclusions reached as to the direction and velocity of propagation. This can be better illustrated by some data used more recently by Dr. Bauer himself (*Terrestrial Magnetism*, December, 1910, Table IV., p. 225), which are much more open to criticism than those from the Coast and Geodetic stations. He takes seventeen disturbances given by Mr. Ellis as recorded at eight stations between 1882–9. Dr. Bauer forms two groups of these stations, the second

containing Bombay, Batavia (107° E.), Zikawei (121° E.), and Melbourne (145° E.). Omitting hours, here are the times in minutes assigned for the commencements at the three last-mentioned stations:—

37·0, 39·7, 8·7, 48·7, 52·7, 42·7, 20·7, 44·0, 4·7, 48·7, 46·7, 18·7, 54·7, 32·7, 24·7, 45·7, 52·7,

31·3, 32·3, 0·3, 45·3, 46·0, 35·6, 21·3, 38·3, −1·2, 41·8, 41·0, 15·3, 50·3, 27·3, 20·8, 41·3, 47·4,

38·4, 33·4, 5·1, 50·0, 55·1, 45·1, 25·1, 45·1, 0·1, 55·1, 45·1, 15·1, 50·1, 35·1, 25·1, 45·1, 45·1,

The number of 7's in the first and second lines, of 3's in the third and fourth, and 1's in the fifth and sixth, tell a tale to anyone who has eyes. It is the treatment of the data, however, to which I would direct attention. Zikawei, though intermediate in longitude, differs usually in the same direction, as regards time of commencement, from Batavia and Melbourne. Its time is earlier than that of Batavia in sixteen cases, and than that of Melbourne in fourteen cases, out of seventeen; and the mean algebraic difference is no less than 5·2 *minutes* in the one instance and 4·6 in the other. Instead of recognising that data such as these are useless for any purposes of high accuracy, Dr. Bauer gets out means from his two central stations and obtains an average of between three and four minutes for the time of going completely round the earth, a time markedly less than the data employed give between Batavia and Zikawei, stations differing by less than 15° in longitude or 38° in latitude.

A final criticism I might mention is this: If disturbances travel round the earth in the way Dr. Bauer supposes, why do not they quite complete the circuit, or even go round several times? In some cases, at least, the amplitudes of commencing movements at stations nearly 180° apart are very similar, so that going half-way round can have had but little effect, and movements with a much reduced amplitude would still have been conspicuous. Earthquake tremors, we know, do go round more than once.

As regards the theory vaguely outlined by Dr. Bauer (pp. 10–11), I am not surprised by his claim that "the careful reader will not fail to observe that . . . [it] is considerably different from that which Dr. Chree imputed to me." But unless I had had prophetic powers, how could it have been otherwise? The earlier theory reached or was based on a definite mathematical equation (*Terrestrial Magnetism*, June, 1910, p. 123), $v = XneD/p$, where v is "the velocity of the moving ions . . . n the number of molecules in a c.c. of gas at a pressure p dynes per sq. cm., e the electric charge carried by an ion, D the coefficient of diffusion of an ion through the gas." Of X Dr. Bauer tells us:—"Regarding the variation of X, some preliminary calculations would appear to indicate that the potential gradient of 1 volt per cm. assumed may be of about the right order of magnitude for the heights concerned" (75 km. is the height finally suggested). My primary difficulties were two. Sir J. J. Thomson, the authority quoted by Dr. Bauer, applies the formula to ions moving in the direction of the field X. Dr. Bauer makes v a horizontal velocity; but "potential gradient" is a term usually applied to the earth's *vertical* field, and 100 volts per metre is the value usually ascribed to it, as an average (probably a low one), at ground-level. Potential gradient, in the usual sense of the term, is known from balloon observations to fall to one-tenth of its ground-level value at heights of a few thousand feet, and at 75 km. it is usually supposed to be infinitesimal. If by "potential gradient" Dr. Bauer means a horizontal field, he should say so explicitly, and explain how it is produced and how he reaches his numerical estimate. As regards his concluding remark on the question of theory, "If Dr. Chree has something better to offer I shall be glad to know it," I labour under the disadvantage of holding the view—antiquated though it may appear to some of my contemporaries—that before advancing a mathematical theory for any supposed phenomenon, it is desirable to make reasonably sure that the phenomenon actually exists.

If we take Dr. Bauer's latest conclusions respecting the fifteen storms he deals with in NATURE, we have nine going east and six west. The mean algebraic difference between the European and American times of commencement, + denoting earlier occurrence in America, is only +0·11 minute. In view of the fact mentioned by Dr. Bauer that the algebraic mean difference between the times deduced by two skilled observers, Drs. Venske and Krogness, for the commencements of six disturbances at Potsdam—one of the best equipped of stations—was no less than 0·4 minute, I think most physicists of experience will recognise the expediency of awaiting something much more decisive before passing a final judgment.

March 4. C. CHREE.

TOGETHER with Mr. O. Krogness, I am just on the way to Khartoum, in Sudan, in order to carry out some researches on the zodiacal light.

In connection with these investigations, we propose to secure some magnetic records with very sensitive apparatus. Special care will be taken to obtain as accurate a time-determination as possible.

For one set of observations we shall use an hour-length of 20 mm.; for another set, with twelve times greater hour-length, records will be obtained between about 5h. p.m. and 3h. a.m. Greenwich mean time.

If at other observatories, especially near the equator, similar *rapid* records could be secured *in the same time-interval*, these would, I think, be of value in deciding the question of the simultaneity or non-simultaneity of abruptly-beginning storms.

Our records are intended to commence on March 20, and will continue for one month.

Similar records will also be obtained by Prof. S. Saeland in Trondhjem. KR. BIRKELAND.

Berlin, March 3.

The Centenary of Bunsen's Birth.

ON March 31 it will be one hundred years since Robert William Bunsen was born, and it has been felt that that occasion should not be allowed to pass without his pupils and admirers in this country giving expression to their veneration of the memory of one of the greatest chemists of our times. A committee has been formed to make the necessary arrangements, and it was intended to celebrate the centenary by a dinner. Unfortunately, the two most distinguished pupils of Bunsen, Sir Henry Roscoe and Sir Edward Thorpe, are at present prevented by indisposition from attending such a celebration. In these circumstances the committee has decided not to proceed with the arrangements for a dinner; but, feeling that the occasion should not be allowed to pass unnoticed, they have resolved to send a signed address to the Heidelberg University from old Heidelberg students in this country, and to place a wreath on the Bunsen monument. May we request those old Heidelberg students who wish to participate in this movement to send their signatures to Prof. H. B. Dixon, of the Manchester University, the chairman of the committee, or to either of the undersigned honorary secretaries?

FRANCIS JONES (Manchester Grammar School).

Manchester, March 11.

Life and Habit.

YOUR correspondent "W. H. M." (NATURE, March 2, p. 12), who believes that it is necessary for newly hatched chicks to learn to eat by imitation, should see a litter of pigs being born. Each little pig the moment that he is outside hurries over the sow's hind legs, and, in the second second of his outdoor life, has a teat in his mouth. If the navel-cord has not got clear of his late home, he tugs away at it with all his might. Seeing such a sight, one might suppose that before birth the creature had been eagerly looking forward to his first breakfast. Or did the splendid prospect flash into his mind only as he found his feet? FRANCIS RAM.

54 St. John's Road, N., March 13.

BIG-GAME SHOOTING IN PATAGONIA AND NEWFOUNDLAND.[1]

"IN Patagonia no one uses the word 'mile,' the distances are so great that all reckoning is counted in leagues," writes Mr. Prichard in his remarkably interesting studies of these desolate, extra-tropical pampas of South America. He contrasts this measurement with what prevails in vast Canada, where the land is so good and so usable that the distances are computed by the acre. "In sterile Patagonia, no farmer can make a living on less than fifteen square miles." In this region he pursued the wild guanaco, belonging, as he does still, to the old school, which thinks it better sport to kill than to photograph. He also shot the guemal, or Patagonian deer—*Cariacus* or *Mazama bisulca*. (The reviewer wishes that some zoologist of commanding physique and authority would settle, as with a hammer or an axe, what is to be the universally accepted generic name or names of this group of American deer.) We are probably still without adequate and correct information regarding the species and varieties of South American deer, and even the size to which some of them attain and the fullest developed type of antler. Mr. Prichard estimates that the Chilian (Patagonian) guemal stands from 36 to 38 inches at the shoulder and weighs about 160 lbs. He states that the specimens of horns in the British Museum are poor. The antlers given in the painted illustrations seem slightly more developed than those in the photographs of the specimens obtained by Mr. Prichard himself, though these are of distinct interest, and perhaps, as he says, much better than anything in the national collection.

The guemal, according to Mr. Prichard, does not range eastwards far from the foothills of the Andes; it is practically absent from the flat, grassy plains of Patagonia.

Besides this deer and the guanaco, Mr. Prichard shot rheas, swans, geese, ibis, condor, Magellan wolves, and saw several fine specimens of puma. He records how this "poor-spirited cat" is frequently tamed and kept as a pet until almost full-grown. One settler near Lake Argentine lived alone in a single-roomed hut throughout the winter with two three-quarter-grown pumas.

As to the Amerindian natives of this region, the Tehuelche, he describes them as a fine race, with large, well-hewn features, their skin of a reddish-brown. But although they average six feet in stature, they have notably deteriorated in physique, from their habit of riding on all occasions and everywhere. A man will not walk a hundred yards, but catches his

The Heads of Canadian and Norwegian Elk contrasted (the lower head is Scandinavian). From "Hunting Camps in Wood and Wilderness."

[1] "Hunting Camps in Wood and Wilderness." By H. Hesketh Prichard. With a Foreword by F. C. Selous. Pp. xiv+274. (London: W. Heinemann, 1910.) Price 10s. net.

horse and rides the distance. So far as the upper part of the body is concerned, the breadth of shoulder and great back and arm muscles demand admiration, but the lower limbs are not proportionately strong.

From the Andes and treeless plains of Patagonia Mr. Prichard whisks the reader to the wildest parts of Labrador and of Newfoundland. After that we have a digression dealing with moose (elk) hunting in Norway, distinctly interesting by the juxtaposition of the scenery, flora and fauna of that country with the north-eastern parts of British North America. Mr. Prichard attempts to show by his illustrations and explanations—or leads us to infer—that a specific difference exists between the elk of northern Europe and the elk of North America, which is cited as *Alces americanus*. But we fancy that zoologists do not claim a full specific difference between these creatures, widely as their habitats are separated at the present day. If the reviewer's memory is correct, Mr. Lydekker himself only claims for the very marked variety of elk in north-eastern Asia the position of a subspecies, *Alces machlis bedfordiae*; and there is distinctly less difference in antlers and other features between the elk of North America and that of Scandinavia, except that no doubt during the last hundred years or so the antlers of the last-named have degenerated, owing to the persecution of the species at the hands of the hunters. Nevertheless, the present difference in size between the Canadian and Norwegian elks is well illustrated by the photographs here reproduced.

Very interesting, and in some respects novel, information is given about the Canadian elk. Mr. Prichard, quoting other authors, touches on the discovery of the gigantic subspecies of elk in that country of marvels, Alaska, the home of the biggest existing bear, the biggest wild dog or wolf (*Canis pambasileus*), and of the biggest elk (*A. m. gigas*), a monster with palmated antlers measuring 76 inches in contradistinction to the 40 inches of an exceptionally good head in Norway, and the average 50 inches of Canada.

Some splendid heads of caribou (Canadian reindeer) were secured by Mr. Prichard and his companion, Mr. Gathorne Hardy. Admirable photographic illustrations are supplied to illustrate the scenery of Newfoundland, a country still all too little known to adventurous travellers seeking for varied phases of landscape beauty. We are made to realise the desolateness of Labrador and yet the charms of its solitude.

"A little lake . . . lay some two miles to the north-west of our camp. Surrounded by trees and seemingly of great depth, it presented the appearance of an unfathomable pit sunk into the roots of the hills. The diver and her brood called ceaselessly upon its waters, bringing back to memory the beautiful and poetic words of Saltatha, the Yellowknife Indian: 'You say the Kingdom of Heaven is good, my father, but tell me, is it better than the land of the musk-ox in summer, when the lakes are sometimes misty and sometimes blue, and the loons cry often? That is good, my father, and if Heaven is better, I shall be willing to dwell there until I am very, very old.' Besides the loon two ospreys haunted the lake, sometimes fishing in the shallow stream which fed it, sometimes winging their way over it and out into the blue distance towards the sea."

Elsewhere in the book there are pen portraits, unconsciously given, of the different guides, hunters, and trackers associated with Mr. Prichard or his companions, some of Newfoundland, some of Labrador, and one or two of Maine (United States) origin. In every case, these simple, virile, honest natures are brought home to us with their quaint diction, shrewd faces, and slovenly clothing, and we realise what good stuff there must be in the manhood of North America. The Mikmak Indians of Newfoundland (recent comers and settlers from the adjoining coasts of Cape Breton and Nova Scotia) are also illustrated verbally and by photography. Mr. Prichard justly points out that it is sentimental nonsense allowing Indians greater privileges in the way of game destruction than are accorded to white men. All alike are citizens of British North America, enjoying the same privileges and subject to the same laws, and it would be no satisfaction to the zoologists of the next generation to be told that the big game was destroyed in Newfoundland by Indians and not by white men.

Altogether this is one of the most attractive and informative works on the big game of the New World which the present reviewer has had the pleasure of reading. The coloured illustrations by Mr. E. G. Caldwell are of remarkable excellence, worthy of Mr. J. G. Millais. Besides being beautiful pictures, they are absolutely truthful, not only in the delineation of beasts, but in the botany of the background. Two of Lady Helen Graham's drawings also deserve special mention; one, of a scene in the Patagonian Andes with guemal deer in the foreground, and another, a study of a bull elk being surprised at night by the light of a lantern.

H. H. JOHNSTON.

THE FANCY FEATHER TRADE.[1]

IN NATURE for December 15, 1910, we reviewed "Aigrettes and Bird-skins," a book written in defence of the bird-plume dealers, in which the name of Mr. C. F. Downham was cited frequently as a witness for the "defendants." This gentleman now appears before us as further counsel on the same side in an address under the second title of "Some Facts and Fallacies in Connection with the Trade in Fancy Feathers," delivered before the London Chamber of Commerce in November last. Part of it has been published as an article in the *National Review*; "The Feather Trade: The Case for the Defence," is an amplified edition. In the number of NATURE just referred to—which may be read in connection with the present observations—we strongly expressed our disagreement with the arguments then put forward. Our view we find independently supported by the *Madras Mail* of September last, which says that "'Aigrettes and Bird-skins' will evoke little sympathy in India. Indeed, it would more probably be read with feelings of derision and ridicule on account of its erroneous and fallacious arguments were its subject not so pathetic."

These words seem to us to sum up very tersely the further defence made by Mr. Downham, who, as managing director of one of the plume-importing firms, can hardly be considered an entirely disinterested advocate. In years past the defence set up by the trade was that the "aigrettes" were artificial, and all the plumassiers' saleswomen were directed to inform tender-hearted buyers that this was really so. Ornithologists were able, however, to nail this deception to the counter so effectually that it had to be abandoned. In its stead arises now the equally spurious statements that they are taken out of the nests, where they form a bed for the eggs; and that in vast heronries in S. America, in Venezeula in particular—whence the largest export comes—

[1] "Some Facts and Fallacies in Connection with the Trade in Fancy Feathers." A Paper read at the London Chamber of Commerce in November, 1910, by C. F. Downham. Pp. 126. (London Chamber of Commerce, Oxford Court, Cannon Street.) Price 6*d*. net.
"The Pros and Cons of the Plumage Bill." A Letter. By James Buckland, of the Royal Colonial Institute.

egrets and other birds are being protected, and that thence, "as for many years it has been known in the trade, a great part of the supply is obtained by collecting the feathers naturally shed by the birds . . . the *opinion* [the italics are the reviewer's] of those in the trade is that considerably more than two-thirds of the supply is so obtained."

These statements are attested by three witnesses: M. F. Geay (now dead); M. Leon Laglaize, who, in being, as it appears, a buyer for a firm of dealers, is scarcely as unprejudiced a witness as might be desired; and M. Grisol. Against their testimony must be set that sent to the Royal Society for the Protection of Birds by H.M. Minister at Caracas (dated January, 1909), who emphatically asserts that M. Laglaize "gives a completely erroneous impression of the conditions under which the industry of collecting plumes is conducted in Venezuela"; of the Consul at Rosario, and of various scientific men, among them, Mr. Quelch (a well-known naturalist, formerly on the staff of the British Museum), who describes the hideously cruel manner of taking the plumes, and declares that "during a residence of seventeen years in British Guiana . . . I have never known or heard of any such method of collection as that described by M. Laglaize"; of Mr. Dresser, author of "The Birds of Europe"; and of Mr. F. Chapman, the distinguished ornithologist of the American Museum of Natural History in New York. These witnesses are convinced that the "moulted plume" theory is as fallacious as the "artificial aigrette" defence, and ornithologists know that egrets do not line their nests with their own nuptial plumes.

It is significant that the collectors' busy time in the swamps is the height of the breeding season. The egrets assume their nuptial plumes before that period begins in August, and shed them only about October, till when there can be few—if any—plumes on the ground to gather. It is well known also that by that date the "aigrettes" have, by reason of wear and tear, become of little or no commercial value.

We find it stated by Mr. Downham that the fancy feather trade has its mainstay in poulterers' refuse and plumes of game birds killed for food; and then by the traders' own testimony, Are not the "aigrettes" wholly artificial? Why all this great outcry that their entire business is in peril should an Act be passed against the import of our finer plumaged bird-skins? The true egret imports can consequently have only a negligible influence on their market. It has been obvious to everyone that during the past year feathers have been worn in women's hats in greater profusion than ever, and that few of them have been those of game or barn-door fowls. Lyre-bird, Argus and Himalayan pheasant, flamingo, peacock, robin, jay, kingfisher, goldfinch, trogon, bird of paradise, and goura pigeon have come under the writer's own notice. Some hats, indeed, were entirely composed of British bird-skins. From Venezeula alone in 1908, 255,900 egrets were exported, and necessarily a large proportion of the offspring of these birds was sacrificed.

Mr. Downham's pamphlet contains short notes on the best-known species of paradise birds by Mr. A. E. Pratt, about which we may be allowed a word from an ornithologist's point of view. It would be interesting to have the evidence—no doubt in his possession—for the statements he makes that these birds are three years old before they produce marketable plumes, and that the Aru islanders watch over the *Paradisea apoda* until they have attained that age. We should hesitate to accept as a fact, without very strong evidence, that the Papuan will stay his hand against any living creature he wants when his opportunity occurs, in hope of some other day meeting it in better condition, and with the chance that his neighbour will forestall him. The fact that the collections of birds by native hunters contain mature and immature skins in equal abundance militates strongly against such a belief.

Our observations upon the Fancy Feather trade were already written before the Pros and Cons of the Plumage Bill reached our hands. All who are doubtful as to their support of this Bill should read Mr. James Buckland's pamphlet. The cruelty of the plumage collector's methods and the enormity of their slaughterings as here set out will appal the reader. He substantiates with exact chapter and verse the precise manner in which the Indian Plumage Bill is systematically evaded by the native plume collectors, because the import of feathers into London is so free and unprohibited. Mr. Downham, in his Case for the Defence, attempted to impune Mr. Buckland's statement made in 1909 that 1,500,000 egrets had been slaughtered in 1908 in Venezuela alone, by asserting that the customs export returns at Ciudad Bolivar were untrustworthy on the point. The British Minister, however, corroborates fully Mr. Buckland, and cuts from beneath them one more of the doubtful testimony of the plume traders, by stating in his report for that year:—"This [the destruction of egrets] is really appalling. . . . If, therefore, we take the average, the number of birds killed last year was 1,538,738; but if we take the highest number it was 2,469,930, and even the lowest accounts for the slaughter of 610,385." Mr. Downham also denies that egret feathers come from Australia. If this be so *now*, it must be because the heronries have been shot out. Mr. Buckland is able to adduce an eye-witness in Mr. Mattingley, the Australian ornithologist, to the methods practised by the Commonwealth gunners, in every respect similar in cruelty and ruthlessness to those of their brethren in Venezuela and elsewhere. Above we have thrown doubt upon the statements of Mr. Laglaize, adduced by Mr. Downham, as to the protection of the heronries in Venezuela and to the collecting of the plumes from the nests. Mr. Buckland goes so far as to assert that, "For sheer power and majesty of lying these statements excel anything ever achieved by Ananias, even at his best."

Mr. Buckland gives equally appalling details as to the destruction of gulls, terns, herons, grebes, pelicans, swans, geese, ducks, ibises, birds of paradise, goura pigeons, and humming-birds, in every region of the globe. "Great heaps, waist high, of dead *Diomedea immutabilis*, and of the black-footed albatross"; "On Marcus Island a party had wiped out of existence one of the largest albatross colonies in the Pacific," are a couple of extracts from him as to the operations of those who labour for the adornment of English ladies. Mr. Buckland's pamphlet supports also our doubt, expressed above, as to the Papuan hesitating to spare any bird he comes across, because it is immature.

It is abundantly evident, therefore, that the testimony, sworn statements, and various excuses brought forward in their attempts to represent this nefarious trade as a pure and legitimate industry, by the textile trade section of the London Chamber of Commerce, are sadly wanting, both in cogency and in veracity.

These latest attempts will, we trust, fail, like the others they have set up, to delay the Plumage Bill, introduced in the House of Commons on February 22, from becoming law "at the earliest possible opportunity," as *The Times* of November 26, 1910, so strongly urges, "which can be found in the new Parliament for business of an uncontentious character."

THE BLACKFEET OF MONTANA.[1]

THE Piegan Blackfeet of Montana are one of the most interesting of the tribes classed as Plains Indians, and it was well worth the while of Mr. Walter McClintock to spend many summers in living among them in order to study and record their customs and religion. The worthiness of his intention and his personal character so appealed to Mad Wolf—one of the prominent men of the tribe—that he adopted Mr. McClintock as his son, hoping for an alliance with a white man that would be productive of sympathy, and fidelity to the welfare of his tribe, and who, by being familiar with their customs, religion, and manner of life, would tell the truth about them to the white race. The present book is a justification of Mad Wolf's action.

FIG. 1.—A Woman Praying to the Sun. From "The Old North Trail."

Mr. McClintock has not written a formal treatise on the Blackfeet, and much that students would like to learn about them has been omitted. A book that would satisfy specialists would not appeal to the public, and doubtless the object of Mad Wolf will be better attained by the narrative form in which the book is cast. The descriptions of climate and scenery, of hunting experiences, and the daily life of an Indian camp give a live and accurate impression, not only of the present condition of the Indians, but enable the reader to gain some idea of what that life was like in the past, when immense herds of antelope and bison roamed over the plains and when the Blackfeet warriors traversed wide tracts of country in quest of plunder and adventure. The old men remember the days of their pride, but soon the memory of them will pass away and meagre records will alone be available in the books of such writers as Catlin, Mackenzie, Grinnell, and McClintock.

Several ceremonies are described, that of the "Beaver Medicine" being illustrated with numerous photographs showing various phases of the ceremony; as these were taken under adverse circumstances in a tipi, they are not so clear as the majority of the illustrations. Most readers will probably be astonished at the number of prayers that are said at these ceremonies, and Mr. McClintock deserves our thanks for having recorded so many of the prayers and chants. It is mainly by having the actual words that we can get a true insight into a ceremony, but, in addition, it is necessary to have a ceremony recorded by a sympathetic observer like the author, for it is quite possible to record every action and yet miss the spirit of a ceremony, as has too frequently been the case. Even at the present day the older Indians are extremely devout and spiritually-minded; this religious attitude of mind combined with a sense of dignity and personal worth are perhaps the most prominent characteristics of the Indian. The present writer has seen a Pawnee and a Blackfeet sacred bundle opened, and he quite endorses Mr. McClintock's statement that "It is difficult for one of the white race to realise the deep solemnity with which the Indians opened the sacred bundle. To them it was a moment of deepest reverence and religious feeling."

The Blackfeet are firm believers in the supernatural and in the control of human affairs by both good and evil powers in the invisible world. The great spirit, or great mystery, or good power, is everywhere and in everything—mountains, plains, winds, waters, trees, and animals. They believe that all animals receive their endowment of power from the sun, differing in degree, but the same in kind as that received by man and all things animate and inanimate. Some, such as the grizzly bear, bison, beaver, wolf, eagle, and raven, are worshipped because they possess a larger amount of the good power than the others, and so, when a Blackfoot is in trouble or peril, he naturally prays to them for assistance. The sun, as the great centre of power and the upholder of all things, was the Blackfeet's supreme object of worship. He saw that every bud, leaf, and blossom turned its face to the sun, that the berries ripened under its warmth, that men and animals thrived under its sustaining

FIG. 2.—Tribal Camp of the Blackfeet. From "The Old North Trail."

[1] "The Old North Trail," or Life, Legends, and Religion of the Blackfeet Indians. By W. McClintock. Pp. xxvi+539. (London: Macmillan and Co., Ltd., 1910.) Price 15s. net.

light, but all perished when it was withdrawn. The devout Blackfoot therefore called upon men, women, and children, and everything that had breath to worship the all-glorious, all-powerful sun-god who fills the heaven with brightness and the earth with life and beauty. The sun-dance was their great annual religious festival, their holy sacrament, the supreme expression of their religion. It must always have its beginning in a woman's vow, made to the sun-god for the recovery of the sick. The account given of the sun-dance is of interest, but far too short for the student.

Various legends and stories are given, and the occasions on which they were told are given, so the tales fit naturally into the pictures of Indian life that Mr. McClintock presents. This is a book that should be read by all who are interested in the ways and thoughts of alien folk, and its value is increased by the very numerous and excellent photographs taken by the author. A. C. HADDON.

PROF. J. H. VAN 'T HOFF.

IT is with the deepest regret that we record the death of Prof. J. H. van 't Hoff, which occurred on March 1, at Steglitz, near Berlin. It was known that his health has not been good for the last two or three years, but the unexpected news of his death at the comparatively early age of fifty-eight years will come as a very heavy blow to the world of science. For a generation the name of van 't Hoff has been familiar to students of science in every part of the civilised world. It would be difficult indeed to mention any branch of modern scientific inquiry which has not been advanced by his fundamental discoveries. Certainly physiology, biology, and geology, as well as every branch of chemistry, owe a deep and undying debt of gratitude to the genius of van 't Hoff. The memory of his name and the influence of his work will outlive the centuries, an integral part of the incorruptible heritage of science.

Jacobus Henricus van 't Hoff was born in Rotterdam on August 30, 1852, his father being a physician of that city. In 1869 he proceeded to the Polytechnikum at Delft, passing through the usual three years' technological course in two years. He was then admitted to the University of Leyden, where he studied until 1872. He continued his studies in Bonn under Kekulé, and in Paris under Wurtz. In 1874, as a pupil of Mulder, he obtained the doctor's degree of the University of Utrecht, with a thesis on cyanacetic and malonic acids.

Van 't Hoff began his teaching career in 1876 as a docent in physics at the Veterinary School at Utrecht. In 1877 he went to Amsterdam, and in the following year was appointed professor of chemistry at the University of Amsterdam. Here he remained for eighteen years.. In 1896 he was called to Berlin as a member of the Imperial Academy of Sciences and as a professor of the University of Berlin. He gave lectures on physical chemistry at the university, but a research laboratory was provided for him by the Academy of Sciences. In this position van 't Hoff continued to work until his death.

Such is a very brief account of the various positions he held during his lifetime. Needless to say, universities, scientific societies, and academies throughout the world vied with each other in honouring him. In 1888 he was elected a foreign member of the Chemical Society of London. He became a foreign member of the Royal Society in 1897, whilst the Physical Society of London elected him a foreign member this year. Amongst others, the universities of Cambridge, Chicago, Heidelberg, Manchester, Greifswald, and Utrecht conferred honorary degrees upon him. The Kaiser bestowed on him the high distinction of the Order "Pour le Mérite." In 1901 the Nobel Prize was awarded to him. Many other honours and distinctions might be mentioned, but enough has been said to show the high esteem in which van 't Hoff was held throughout the world. Like all great men of science, the true story of his life is, however, to be found in his researches.

Under the influence of Kekulé, Wurtz, and Mulder, the earliest work of van 't Hoff relates to organic chemistry. But here his genius soon enabled him to strike a note of extraordinary originality. While still engaged with Mulder in synthetic organic work, he published in 1874 a short pamphlet in Dutch, in which he unfolded his new ideas concerning the extension of organic structural formulæ to three-dimensional space, and the relation between optical activity and the presence of an "asymmetric" carbon atom. In 1875 this appeared in an enlarged form under the title "La Chimie dans l'espace," a German edition, with a preface by J. Wislicenus, appearing in 1877 ("Die Lagerung der Atome im Raume"). Thus was born van 't Hoff's famous theory of the "tetrahedral" carbon atom and the science of stereochemistry. As all the world now knows, van 't Hoff's new ideas found many opponents. In particular Kolbe, who was an opponent of structural chemical formulæ in general, attacked the new ideas and their author with great virulence. But the "lame Pegasus" which the young lecturer at the Utrecht Veterinary School had bestridden was not so lame as Kolbe imagined, and van 't Hoff's ideas gradually triumphed. The warm support of Johann Wislicenus and the work of himself and his school greatly contributed towards the recognition and development of van 't Hoff's ideas.

Not long after the appearance of the "Chimie dans l'espace," van 't Hoff published a very remarkable and little-known book, entitled "Ansichten über die organische Chemie." In it he sought to give the whole of organic chemistry a strict and logical arrangement, wherein both old and new facts should find their proper place. At the same time he emphasised the necessity for a *quantitative* study of the course of chemical reactions, and developed the fundamental equations of chemical kinetics and equilibrium on the basis of the law of man-action. Although in some respects van 't Hoff was preceded here by Guldberg and Waage, as well as by Harcourt and Esson, we perceive here the beginning of that long and masterly series of experimental and theoretical researches, whereby van 't Hoff raised the whole subject of chemical dynamics to the level of an exact and well-ordered branch of science. In the celebrated and now classical "Etudes de Dynamique chimique" (1884), van 't Hoff gave a collected account of these researches. Here is to be found a systematic study of the velocity of reactions, *as dependent on the number of reacting molecules*, a method for determining the number of reacting molecules from the experimental data, an exhaustive study of the "disturbing" actions, and an investigation of the influence of temperature on velocity of reaction. Masterly as was the treatment of chemical kinetics here set forth by van 't Hoff, one would err grievously in imagining the "Etudes" to contain nothing else. Nearly one-half of the monograph was devoted to chemical equilibrium and affinity. In this portion van 't Hoff abandoned the purely molecular-kinetic standpoint, treating the subject from the point of view of thermodynamics. One finds here the classical treatment of the equilibrium of "condensed" phases, and of the influence of temperature and pressure thereon. Here is also to be found the enunciation of van 't Hoff's

famous "Principle of Mobile Equilibrium":—"Tout équilibre entre deux états différents de la matière (systèmes) se déplace par un abaissement de la température du côté de celui des deux systèmes, dont la formation développe de la chaleur."

Finally, in the chapter on affinity, perhaps the most remarkable and original part of the whole book, van 't Hoff shows for the first time how the chemical forces operative in reaction can be measured and compared.

But van 't Hoff's greatest triumph was still to come, though we may regard the application of thermodynamics to chemical equilibrium to be found in the "Études" as preparing the way for it. In 1886 van 't Hoff's famous paper on "The Laws of Chemical Equilibrium in the Dilute, Gaseous or Dissolved State of Matter" was published in the Transactions of the Swedish Academy of Sciences. This was quickly followed by two other fundamental papers, one on "A General Property of Dilute Matter," and one on "Electrical Conditions of Chemical Equilibrium." In 1887 there appeared in the first volume of the "Zeitschrift für physikalische Chemie" an abstract of the above, bearing the title "Die Rolle des osmotischen Draches in der Analogie zwischen Lösungen und Gasen."

It would be impossible to exaggerate the fundamental importance of these researches. By developing the idea of osmotic pressure on the basis of the experimental work of Traube and Pfeffer and by an application of the laws of thermodynamics, van 't Hoff was enabled to put the whole subject of physical and chemical equilibrium in dilute solutions on a sure and simple basis. The extraordinary analogy which he discovered, and showed also to be thermodynamically necessary, between the laws connecting the osmotic pressure, molecular concentration, and temperature of a dilute solution and the corresponding simple gas laws, played a profound part in this development.

Although the laws of equilibrium in solutions had been given by Gibbs previously in a generalised thermodynamical form, and had been applied by Helmholtz to cases where the partial vapour-pressures as functions of the concentration were empirically known, van 't Hoff was the first, by means of the concept of osmotic pressure and the simple laws relating to it, to create a practically useful thermodynamical theory of dilute solutions. In doing this he demonstrated the insufficiency of Guldberg and Waage's laws in its original form, and paved the way for the electrolytic dissociation theory of Arrhenius and its development and application by Ostwald and Nernst. In fact, the simple interpretation which the theory of electrolytic dissociation gives to the coefficient i of van 't Hoff's thermodynamical equations remains to-day, as it was twenty years ago, one of the chief foundations of this theory.

The theory of dilute solutions, as developed by van 't Hoff, rendered inestimable service to the general development of chemical science in the sure thermodynamical basis which it gave to the previously empirical methods for determining the molecular weights of dissolved substances. It would be difficult indeed at the present day to discover any branch of chemical, physiological, or biological science which does not owe something to the fundamental advances made by van 't Hoff in the theory of physical and chemical equilibrium in dilute solutions.

The last great period of van 't Hoff's scientific activity was mainly devoted to a study of heterogeneous equilibrium, especially as regards the conditions determining the formation and decomposition of double salts, and the crystallisation of complex mixtures. The first fruits of these researches appeared in collected form in his "Vorlesungen über Bildung und Spaltung von Doppelsalzen" (Berlin, 1897). Here for the first time were set forth in lucid and masterly manner all the conditions of temperature and concentration which determine the crystallisation of double and single salts, with many and varied applications to special cases, culminating in the unravelling of the complicated phenomena presented by the double racemates of Scacchi and Wyrouboff. Another striking case was the working out of the conditions of formation of Schönite. The book also contains an account of the beautiful experimental methods worked out by van 't Hoff for the determination of transition-points.

The researches summarised in this book may be regarded as forming a fitting prelude to the great work which van 't Hoff undertook during his residence in Berlin, namely, the investigation of the formation of oceanic salt deposits, with special reference to those occurring at Stassfurth. This great geological problem was undertaken in collaboration with Meyerhoffer, and with the help of a number of research students. It reduced itself practically to the determination of the heterogeneous equilibria occurring in solutions containing the chlorides, sulphates, and borates of sodium, potassium, calcium, and magnesium. Proceeding step by step from the simple to the more complex solutions, and employing all the methods which he had previously worked out for determining equilibria and transition-points, van 't Hoff slowly but surely succeeded in unravelling the gigantic problem which he had set himself to solve. It would be quite impossible here to convey even a faint idea of the complexity of the task, and of the genius which enabled van 't Hoff to attack it so successfully. Probably no part of his life-work is less generally known than the wonderful series of researches which issued from his laboratory at Charlottenburg during the years 1896–1909, and yet it may be safely said that these researches constitute an absolutely fundamental advance not only in physical and inorganic chemistry, but also in scientific mineral synthesis and rational *experimental* geology. They will for ever remain the classical model for the application of the methods and principles of heterogeneous chemical equilibrium to the science of experimental mineralogy. Van 't Hoff published a collected account of these researches in two small volumes with the modest title, "Zur Bildung der ozeanischen Salzablagerungen" (Vieweg, Brunswick, 1905 and 1909.) This magnificent work on the Stassfurth salt deposits was the last great problem to which van 't Hoff devoted his attention. It forms a fitting close to a life of strenuous work and extraordinary scientific fertility.

In spite of the continuous labour involved in his daily work in the laboratory and in the publication of his researches, van 't Hoff found time, during his residence in Berlin, to publish his "Vorlesungen über theoretische und physikalische Chemie" (Vieweg, Braunschweig). This will long remain a standard work on theoretical chemistry. It is characterised by great originality of treatment, remarkable breadth of outlook, and that close and intimate relationship of fact and theory which was always one of van 't Hoff's salient characteristics.

Of other works may be mentioned a short summary of the "Theory of Solutions," published in Ahrens' "Sammlung chemischer Vorträge" (1900), and the delightful "Acht Vorträge über physikalische Chemie" (Vieweg, 1902), an embodiment of the lectures which van 't Hoff was invited to give at the University of Chicago in 1901 on the occasion of

the decennial celebrations of the foundation of that university.

Since its foundation, in 1887, van 't Hoff's name has been associated with the "Zeitschrift für physikalische Chemie" as one of its editors. In 1899 the thirty-first volume of that journal was devoted to a "Festschrift" in honour of the twenty-fifth anniversary of his doctorate, many of his old pupils and many other men of science contributing papers in honour of the occasion.

The above is but a brief and meagre account of the life-work of one of the greatest geniuses the world has ever seen. It would take many pages of this journal to convey anything like an adequate idea of the extent and originality of his researches. But the only true appraisement of van 't Hoff's work and influence is to be found in the living science of to-day and in the minds of countless thousands of scientific workers. As time rolls on his name and his work will stand out ever more prominently in the story of the development of chemical theory. We are still too near the mountain to be able to appreciate fully the grandeur of its heights.

The present writer is one of those whose privilege it is to have worked under van 't Hoff. That was in the days at Charlottenburg, when the investigation of the oceanic salt deposits was just beginning. Every day endeared van 't Hoff to the small band of workers in his laboratory. His joy in his work, the simple and unaffected friendliness of his nature, and the marvellous power of his mind affected us most deeply. All who worked with van 't Hoff quickly learned to love and respect him, and we were no exception to the rule. The kindliness of his heart and the simple charm of his manner were no less characteristic of him than the genius that is known to all.

With the passing away of van 't Hoff chemistry loses one of her greatest men. His was indeed one of the master-minds of science. All his work was characterised by the penetrating insight and the wide creative outlook of a lofty and commanding genius. When one reflects on the vast regions of knowledge which he either created or systematised and marvellously developed—stereochemistry, chemical dynamics, chemical equilibrium and affinity, the laws of solutions—the thought occurs to one that future ages will see in him the Newton of chemistry.

However that may be, chemical science, which to-day so deeply mourns his loss, will ever rank van 't Hoff amongst the greatest chemists of any age.

F. G. D.

NOTES.

THE death of the able and accomplished naturalist Prof. Félix Plateau occurred at Ghent on March 4 after a long and painful illness. Prof. Plateau only recently retired from the active duties of his chair of zoology in the University of Ghent, and was appointed *Professeur émerite*. From his earliest days he pursued the study of his favourite science with indefatigable energy, devoting himself, in the main, to the arthropods, and especially to the Insecta and their physiological and physico-chemical aspects. Though of slight build and apparent delicacy, yet he was enabled, since he visited the British Association in Liverpool in 1870, to carry out a long series of researches for more than forty years, enriching the literature of his subject in a noteworthy way with both pen and pencil. His labours embraced such subjects as the vision of arthropods (including insects), respiratory movements of insects, centre of gravity in insects, functions of antennæ, physico-chemical observations on aquatic insects, movements and innervation of the central organs of the circulation in insects, errors committed by Hymenoptera in visiting flowers, means of protection in Abraxas, observations as to whether the syrphides admire colours of flowers, and a large number of researches on the behaviour of insects with regard to flowers, natural and artificial, besides numerous papers on allied subjects. These memoirs were illustrated by his facile pencil, and were carried out with great labour and ingenuity by means of apparatus devised by himself. Prof. Plateau was a member of the Royal Academy of Sciences of Belgium, and was much esteemed for his amiability and wide culture. He will be greatly missed as an earnest and indefatigable investigator of that side of entomology from which modern science has been enabled to draw safe deductions instead of vague suppositions. He leaves a widow and several sons and daughters.

IT is difficult to believe that Viscount Dalrymple was serious in asking the First Lord of the Admiralty in the House of Commons on March 8 "whether he would arrange for the fleet to carry out their heavy gun-firing practice round the coast at some other period of the year than in the middle of harvest time, when the resulting heavy rain may cause serious loss to the farming community." Mr. McKenna answered the question evidently in the belief that it was asked in good faith; he began by saying "there is no evidence that the firing causes heavy rain," and we do not need to concern ourselves with the rest of the reply. No doubt, whether Lord Dalrymple was jesting or not, many people still cling to the belief in the power of explosions to produce rain, and we referred last week to several cases in point. In the new number of *Symons's Meteorological Magazine* Mr. F. Gaster points out that the firing of big guns is carried on more frequently at Shoeburyness than at any other point on the coast, but that the mean annual rainfall at Shoeburyness, and on the coast of Essex generally, is the lowest in the British Isles. This seems to be the most convincing form of reply to those who profess to believe, or do believe, in the efficacy of gun-firing to produce rain.

LORD CRAWFORD presided at the meeting on March 8, at the British Museum, to present Sir Edward Maunde Thompson, late director and principal librarian, with his portrait, painted by the president of the Royal Academy (Sir Edward Poynter), who is also a trustee of the museum. Among the subscribers were the Archbishop of Canterbury (appointed a trustee in 1884 by Queen Victoria), who made the presentation, the Speaker, Sir Henry Howorth, Lady (John) Evans, and the officers and assistants of the museum, including Mr. F. G. Kenyon (director and principal librarian), Mr. L. Fletcher, F.R.S. (director of the natural history departments), Mr. A. R. Dryhurst and Mr. C. E. Fagan (assistant secretaries), Mr. Basil H. Soulsby, and many others. The portrait will be exhibited at the Royal Academy, and may one day join the collection of portraits of principal librarians and trustees in the board-room at the British Museum, which includes the portrait of Sir Antonio Panizzi by G. F. Watts, and Sir Joseph Banks by Lawrence.

DR. ÖSTEN BERGSTRAND, for some time observer at the Upsala Observatory, Sweden, has been appointed professor of astronomy in the Upsala University and director of the observatory.

THE Belgian Maritime Association has engaged M. H. Phillipot, assistant in charge of the meridian service at the Uccle Observatory, as professor of astronomy on board

the Belgian naval college ship *L'Avenir*. The engagement is for six months, and the ship left Sunderland for Montevideo on March 9.

THE next triennial prize of 300*l.*, under the will of the late Sir Astley P. Cooper, will be awarded to the author of the best essay or treatise on "The Means by which the Coagulability of the Blood may be Altered." Essays, written in English, must be sent to Guy's Hospital, addressed to the physicians and surgeons, on or before January 1, 1913.

THE annual congress of French geographical societies is to be held this year at Roubaix, during the exhibition in that town, from July 29 to August 5, under the presidency of Prince Roland Bonaparte.

AT the recent meeting of the Australasian Association for the Advancement of Science in Sydney, the Mueller memorial medal was awarded to Mr. Robert Etheridge, curator of the Australian Museum, in recognition of the value of his numerous contributions to the palæontology and ethnology of Australasia.

A REUTER message from Portici states that on March 12 a portion of the crust around the crater of Vesuvius, 300 metres long and 24 metres in thickness, suddenly subsided, causing an appreciable shock of earthquake. Small portions of the crust continue to fall in, and a canopy of ashes is hanging over the mountain. As the result of the collapse the crater seems to be lower, and Vesuvius bears the appearance of having been decapitated.

WE learn from the Vienna correspondent of *The Times* that on March 9 the Austrian Academy of Sciences held a special sitting to celebrate the fiftieth anniversary of the appointment of the Archduke Rainer to be its curator. The Archduke marked the occasion by giving a sum amounting to about 4166*l.* to the academy as an endowment for those members who may need to keep in touch with the progress of their special branches of study in other countries.

ON Tuesday next, March 21, Dr. M. Aurel Stein will deliver the first of a course of three lectures at the Royal Institution on "Explorations of Ancient Desert Sites in Central Asia." The Friday evening discourse on March 24 will be delivered by Sir David Gill on "The Sidereal Universe," on March 31 by Prof. H. S. Hele-Shaw on "Travelling at High Speeds on the Surface of the Earth and above It," and on April 7 by Sir J. J. Thomson on "A New Method of Chemical Analysis."

PROF. VLAD. KULCZYŃSKI, the distinguished arachnologist, of Cracow University, is just concluding the thirtieth year of his scientific activity. The physiographical committee of the Cracow Academy of Sciences intends to commemorate this anniversary by presenting to him an album with photographs of his fellow-zoologists and friends, who are invited to send their photographs, together with at least 20 kronen (=17*s.*), to Prof. E. Godlewski, Cracow University. The surplus of the capital remaining after paying for the album will be used to cover the costs of editing the work "The Arachnological Fauna of Poland and the adjacent Countries." The special meeting of the physiographical committee, when the album is to be delivered to Prof. Kulczyński, will be held on March 24 at midday.

AT a special meeting lately held in the Berlin Royal Museum of Natural History, the committee for the exploration of the dinosaur-bearing deposits of German East Africa exhibited a few of the more remarkable specimens already received. The collection consists chiefly of the remains of Sauropoda, some much larger than the gigantic species of North America. One humerus measures more than 2 metres in length, and some of the cervical vertebræ are twice as large as those of Diplodocus. The leader of the exploring party, Dr. W. Janensch, reports the discovery of two new localities in which dinosaurian bones are abundant, and the chairman of the committee, Prof. W. Branca, is making an appeal for the gift of additional funds to continue the work.

THE discovery of Archæocyathinæ in a piece of limestone brought from the Antarctic continent by the Shackleton expedition, has excited renewed interest in these problematical Cambrian fossils. A typical series of specimens, obtained by Mr. Griffith Taylor, from South Australia, has accordingly been arranged for exhibition, with explanatory diagrams, in the Department of Geology, British Museum (Natural History). These organisms have now been discovered in the oldest fossil-bearing rocks in nearly all parts of the globe. Their form is that of two cups, one within the other, and their skeleton consists of granular calcite, not of spicules. The cups are pierced with perforations, and the space between the two is more or less subdivided by radial partitions and horizontal bars or plates, which are also perforated. The whole structure of the skeleton suggests that currents of water originally flowed through it, but its non-spicular construction prevents its reference to a sponge. It has even been compared with a calcareous alga, such as the existing Acetabularia, but the differences are so important that it is difficult to conceive of Archæocyathus as a primitive plant. In the museum the collection is placed between the Protozoa and the sponges.

WE record with regret the death, on March 9, of Colonel John Pennycuick, C.S.I., late R.E., at the age of seventy years. His name is best known in connection with the Periyar Diversion and the construction of the huge dam across the upper waters of the river Periyar, in the Travancore territory, and taking the water from the lake thus formed through a tunnel in the Western Ghats across to the opposite slope to supply the areas of the Madura district. Colonel Pennycuick was at the head of the Madras Public Works Department for several years, and retired in 1896, when he became president of the Royal Indian Engineering College at Coopers Hill, and held the post until the summer of 1899.

THE annual general meeting of the Ray Society was held on March 9, Dr. R. F. Scharff being in the chair. The report of the council stated that by the issue last year of part viii. of the "British Nudibranchiate Mollusca," for 1909, and of vol. ii., part ii., of the "British Annelids," for 1910, the publications had been brought up to date, and that for the present year two volumes were already in preparation, being vol. iv. of the "British Desmidiaceæ," with about thirty plates, and vol. iii. of the "British Tunicata," with sixteen plates, fourteen being coloured, completing that work. The balance-sheet showed a balance in hand of 55*l.* 2*s.* 8*d.*, with an investment of 1250*l.* Consols. The Right Hon. Lord Avebury was re-elected president, Dr. F. DuCane Godman treasurer, and Mr. John Hopkinson secretary.

AT the meeting of the Royal Geographical Society on March 13, Dr. T. G. Longstaff described his crossing of the Purcell Range in British Columbia in the course of last summer. This range lies parallel to, but is distinct from, the Selkirk Range, and both, while situated along-

side the Rocky Mountains, are much older than the latter, representing in this region the original main axis of the North American Cordillera. The Purcell Range, like the Selkirks proper, attains no great height in its southern portion, but the northern half rises well above the snow-line in numerous glacier-clad peaks. The author was accompanied by Mr. Wheeler, a well-known Canadian mountaineer and topographer, who with theodolite and survey-camera made large additions to the survey of the region where the Dominion Government has of late suspended work to press forward that in more fertile areas. A large glacier which descends to the valley floor amongst the timber was visited, and its present phase was found to be one of retreat. Stations were occupied up to more than 8000 feet, and from the photographic survey 11,489 feet was determined as the height of the principal peak. This may be Mount Nelson or Mount Hammond, which, however, the author thinks may be identical. By the latter part of September it was necessary to leave the high valleys, after Mr. Wheeler had completed a considerable amount of surveying, and after the expedition had gained a general knowledge of the Purcell range and the location of its highest and most glaciated portions.

Mr. R. A. Leslie Moore amused his audience at the Royal Society of Arts on February 24 by an account of Indian superstitions—omens, the evil eye, spooks and goblins, mystic animals, birds, insects, reptiles, trees, and so forth. The learned student of custom and tradition who is familiar with the abundant literature gathered on this subject in India will find little that is novel in this pleasant but rambling paper, or in the discursive remarks of Sir G. Birdwood and other Indian authorities which followed. But the paper will have a useful effect if only by directing attention to the vast, and still only partially garnered, material which India can supply.

The recent death of Sir Francis Galton, the founder of the science of eugenics, naturally leads to a discussion in *The Fornightly Review* for March on the relation of eugenics to Mendelian genetics, contributed by Mr. G. C. Nuttall. The latter is working, and apparently on successful lines, to bring law and order into the inchoate mass of the facts of heredity; the former is striving to teach man to use his conscience, as well as his intellect, in dealing with this new knowledge. The writer believes it to be proved that feeble-mindedness could practically be stamped out in two generations if the State rigorously determined to check the perennial flow of the strain of the unfit into our national life. All this may be true; but the voice of the teacher is still that of one preaching in the wilderness. The remedy involves the seclusion of all persons defective in mind or body, a drastic method which our democracy, largely swayed by sentimental emotions, seems, for the present at least, not prepared to adopt.

The Public Works Department of the Government of Egypt has published a second edition of the List of Animals in the Zoological Gardens at Giza, near Cairo, compiled by Captain Stanley S. Flower, the director, and illustrated by twenty plates reproduced from photographs. The names of species inhabiting Africa (inclusive of Madagascar), Arabia, and Syria are respectively indicated by an asterisk. An important feature of the work is a record of the number of years specimens have lived in the gardens since Captain Flower took over charge in 1898. At the annual census, taken in October, 1910, the total number of animals living in the gardens was 1464, referable to 391 species, both these figures being higher than in any previous year.

In No. 1796 (vol. xxxix., pp. 489–93) of the Proceedings of the U.S. National Museum, Mr. R. L. Moodie describes a labyrinthodont from the Kansas Coal Measures, which is of interest alike on account of the rarity of such remains in that formation and from its own intrinsic characters; for this labyrinthodont, which is described as a new genus and species, *Erpetosuchus kansensis*, differs from all its relatives in the presence of a pair of oval vacuities on each side of the inner wall of the lower jaw, comparable to those of a crocodile, while it is further distinguished by the uniform character and shortness of its teeth. It is assigned to the family Labyrinthodontidæ. Greek scholars will regret that the genus was not named Herpetosuchus

Taking as his text a statement by Mr. C. B. Devonport, to the effect that self-coloured fowls, as being more conspicuous, tend to be eliminated by natural enemies, whereas barred birds, on account of being less conspicuous, are more immune to attack, Dr. Raymond Pearl, in the February number of *The American Naturalist*, states that he has found the alleged contrast in regard to conspicuousness to be well founded. On the other hand, as the result of experiment, he denies the truth of the theory based on these facts. "We have been prone," he writes, "to agree that because an organism was coloured or formed in such a way as to be inconspicuous, it was, therefore, necessarily protected from attack by its enemies. . . . The logic of such reasoning is flawless. . . . But a conclusion may be perfectly logical and still not true. In the study of protective coloration, including mimicry, it is essential that a discovery that an organism is to human eyes inconspicuous or not readily distinguishable from some other organism shall not be considered the final goal."

The recent appearance in vast numbers of the giant African snail *Achatina fulica* in Ceylon forms the subject of an article by Mr. E. E. Green in the February issue of *The Zoologist*. This bulimus-like species is a native of East Africa, but appears to have been introduced many years ago into Mauritius, where it is now common. To Calcutta it was introduced about half a century ago, and by 1877 was abundant in the gardens of the houses in Chominghi, while it had also crossed the Hughli to Howra and Barrakpur. About ten years ago a collector introduced the species on his estate in the highlands of central Ceylon, but soon after attempts were made to exterminate the intruders, and it was believed effectually. It appears, however, that some escaped destruction, and of these a couple were recently carried down with vegetables to the low country. Here they increased to such an amazing extent, over an area of about five square miles, that their numbers were to be reckoned by millions, no fewer than 227 being counted in a cluster on the stem of a cocoanut palm in a length of about 6 feet. Naturally the natives were in fear that their crops would be devastated; but, as a matter of fact, little or no serious damage has been inflicted, and it appears that the species largely acts the part of a scavenger, so that in some degree, at any rate, its introduction is a benefit. The adults are attacked by a terrapin of the genus Nicoria, and in its young stages the species probably has many foes. The enormous fecundity of these snails on their first introduction to the lowlands was probably a temporary phenomenon, and their numbers now appear to be diminishing.

Dr. Rudolf von Ritter-Záhony gives (Fisheries, Ireland, Sci. Invest., 1910, iv.) an account of the Chætognatha taken during the years 1905–6 off the coast of Ireland. As was to be expected in the surface waters

of the temperate zone, the group is almost solely represented in the Irish epiplankton by *Sagitta bipunctata* and *Spadella cephaloptera*; *Sagitta serratodentata* also occurs, but is comparatively rare, and only a few young *Eukrohnia hamata* were observed. In the mesoplankton the first two forms were entirely absent; *E. hamata* predominated there, and with it were nine other species, some entirely confined to the mesoplankton, while others were found there only in the adult condition after having passed through their earlier stages of development in the epiplankton of warmer seas. In the same publication (v.) Messrs. E. W. L. Holt and L. W. Byrne give a list of 103 fishes of the Irish Atlantic slope, taken beyond the 100-fathom line, with references to the memoirs in which they are described.

An insect pest of the camphor trees on the main island of Japan and Formosa, in the shape of a new species of the Psyllidæ, *Trioza camphorae*, is described by Prof. C. Sasaki in the Journal of the College of Agriculture, Tokio University (vol. ii., No. 5). The larvæ give rise to flattish button galls on the leaves.

The first article in vol. xxviii. of the Journal of the College of Science, Tokio University, is devoted to short botanical studies from the tropics, by Prof. M. Miyoshi. Discussing the characters of tropical foliage leaves, he notes the tendency to produce firm entire leaves with a smooth or shining surface. Data are also supplied with regard to the manner in which leaves are wetted by rain. Another note refers to the Indian cherry tree *Prunus Puddum*, confirming the suggestion made by Sir J. D. Hooker that it is allied to the Japanese mountain cherry *P. pseudo-cerasus*, which it resembles in flower characters; from *P. campanulata* it differs markedly in the form of the fruit.

A third paper embodying researches upon the sexual organs and reproduction in the cycad, *Dioon edule*, in this case dealing with fertilisation and embryogeny, is contributed by Prof. C. J. Chamberlain to *The Botanical Gazette* (December, 1910). In Mexico, fertilisation takes place during the month of April. The sperms escape through the ruptured end of the pollen tube with a small amount of liquid of high osmotic value, and one nucleus enters the egg, often slipping out of its ciliated sheath as it squeezes past the neck cells; it is suggested that the passage is prepared by the liquid issuing from the pollen tube, which plasmolyses the neck cells. After fertilisation a number of free nuclei are formed; then there is a distinct but evanescent formation of cell walls throughout the entire proembryo which only materialises into walls at the basal end where suspensor and embryo are differentiated.

Experiments are continuously being conducted in the West Indies to obtain varieties of sugar-cane suited to the various soil and climatic conditions in the different districts of the islands. Numbers of new canes are raised from seed annually, and promising plants are carefully propagated; analysis is then made of the juice. Details of experiments conducted on these lines are given in Pamphlet No. 66, recently issued by the Imperial Department of Agriculture for the West Indies.

The official forecast of the wheat crop of South Australia is put at 11·91 bushels per acre, this being 1·35 bushels fewer than the actual yield obtained twelve months ago. So late as last September it was thought that the present harvest would be 20 per cent. greater than the previous one, but an unusually severe attack of disease, locally known as "takeall," has since set in, and has in some cases destroyed entire crops. The disease is caused by the fungus *Ophiobolus graminus*, an interesting account of which occurs in *The Journal of Agriculture for South Australia* (No. 5). It is urged that a plant pathologist is needed for the study of crop diseases, which, according to the writer, cause a loss of nearly half a million of money each year in South Australia alone.

From the report of the Botanic Station, Experiment Plots and Agricultural School, Dominica, 1909–10, we learn that the general conditions of the gardens is satisfactory. A strong feature of the work is the distribution of material for planting purposes. More than 79,000 plants were sent out during the year, as well as large numbers of seeds. The experiments with economic plants include, among others, trials with spineless limes, varieties of citrus plants, Para rubber, and grafted cacao. The lime industry appears to be well established, and the conditions of production are steadily improving. Para rubber continues to do well in the wet districts of the island. Much remains to be done in improving the cacao industry; it is considered that the yield might be considerably higher if better methods were more generally used.

Dr. E. J. Butler has been appointed director of the Agricultural Research Institute and College, Pusa, in place of Mr. Coventry, who is now Inspector-General of Agriculture in India. The annual report of the work of this institution describes the chief investigations carried on by the various departments. In the botanical department Mr. and Mrs. Howard are continuing their work on wheat, and are obtaining very promising results. Dr. Leather's work on the water requirements of plants is calculated to afford information valuable alike to the agriculturist and the irrigation engineer. Much attention is paid in the entomological department to industries that depend on the products of insects, eri, mulberry, tussor silk, and the cultivation of lac being the chief. The mycologist has carried out important investigations on the blister blight of tea and the palm disease in the Godavery Delta. A bacteriological section has been added, and a cotton expert appointed.

In the *Bolletino della Società geografica Italiana* for February, Major A. Tancredi, who has done much to advance our knowledge of the climate of Eritræa, describes the salt plain lying to the east of the Abyssinian tableland. Situated at about 110 metres below sea-level, and forming an area of inland drainage, it has a mean temperature of about 31° C., while the maximum in summer is said to reach 50° C. From the salt deposits here formed, the Abyssinian merchants obtain the blocks of rock-salt which are used as currency throughout the country, rapidly rising in value towards the more remote western parts of the tableland. The volcano of Ert-Alé to the southward was seen from the hills above the Saline of Assale, but was not visited.

From the results of the Swedish expedition to Spitsbergen in 1908 under Prof. G. de Geer, we have received a first part containing the hydrographical observations by N. von Hofsten and S. Bock. The temperature and salinity of the sea were determined at about thirty points both on the outward and the homeward voyage. These factors showed a marked increase on the conditions which existed about 1902, when ice in August still surrounded the southern portion of Spitsbergen, and indicated a return to such as existed in 1898, when the Nathorst expedition could sail round Spitsbergen and visit Gills Land. The topography of Eisfjord, on the western coast of Spitsbergen, was studied during the second half of July and

August, as well as the hydrographical conditions, which showed that the warm salt Atlantic water flows into the fjord, and has there its temperature and salinity lowered by the glacier ice descending from the land.

In the Monthly Review of the Seismic Activity of the Earth's Crust, issued by the Kaiserl. Hauptstation für Erdbebenforschung in Strassburg, we find for June, 1910, references to forty-seven earthquakes. A few of these were destructive, but the greater number appear to have been local tremors. For each of these disturbances we have the date, the time (local and Greenwich), the character of the movement, its duration, direction, and general remarks. The fact that Japan records, on the average, 100 earthquakes per month, and the world probably experiences several thousands, it seems extremely likely that this publication will increase in size, but, as it stands, it must frequently be of great value in the interpretation of teleseismic records.

The Canadian Department of Mines has issued two advance chapters of the annual report on the mineral production of Canada during the year 1909. Each chapter is by Mr. John McLeish, chief of the division of mineral resources and statistics; one deals with the production of iron and steel in Canada in 1909, and the other with the production of coal and coke. The former industry showed a very satisfactory and steady growth as compared with previous years, but the coal-mining industry was marked during 1909 by a decreased production in Nova Scotia and an increased production in the western provinces, resulting in an aggregate decrease for the whole of Canada of 384,836 tons (short tons of 2000 lb.), or about 3½ per cent. Although iron ores are of wide occurrence throughout Canada, being found practically in every province, the development of these resources has not kept pace with the growth of Canadian metallurgical industries. About 17 per cent. only of the iron ore used in Canadian furnaces during 1909 was of domestic origin. Much of the coke and limestone also was imported, so that Canadian iron industries are now, and have been for a number of years, largely dependent on imported raw material. Coal mining has long been the most important of Canada's mining industries, and in 1909 is credited with 27 per cent. of the total mineral production of the country. The output in 1909 is more than twice that of ten years ago, about four times the output of twenty years ago, and nearly ten times the production of 1879. Notwithstanding its large coal resources, Canada's total coal production in 1909 was only about 56·4 per cent. of the estimated consumption, and the additional requirements were supplied by imports, chiefly from the United States.

The meteorological chart of the Indian Ocean for March, issued by the Meteorological Committee, quotes several cases of phosphorescent seas that have been observed in recent years. Among the most interesting is one forwarded to the Danish Meteorological Institute by Captain Gabe in the Strait of Malacca in June, 1909. Luminous waves were observed travelling from west to east, and gradually assumed the form of long arms, with dark intervals between them. These issued from an apparent focus, around which they rotated, which seemed to be on the horizon. An illustration of the phenomenon shows that the beams of light were somewhat curved, the concave edge being in the direction of rotation (clockwise). The brightness lasted about a quarter of an hour. A somewhat similar case of rotatory light system was observed by Captain Breyer in August last near the Natuna Islands, but the direction of rotation round the apparent focus in this instance was anti-clockwise.

In the *Verhandlungen der Deutschen Physikalischen Gesellschaft* for February 15, Prof. M. Planck removes one of the difficulties in the proof of his expression for the radiation from a perfectly black body. It will be remembered that the proof depended on the assumption that a simple Hertz oscillator could only possess an amount of energy which was an integral multiple of a certain small quantity of energy, or, in other words, that energy was atomic in structure, and emission and absorption of energy must take place by "atomic" steps. In the present paper Prof. Planck shows that, although emission must still take place in steps, absorption may be taken as continuous, and the amount of energy possessed by an oscillator at any instant may be a fractional number of "atoms." If, however, the probability that the oscillator emits an "atom" of energy be taken proportional to the whole number of "atoms" of energy it possesses, the fractional excess being disregarded, the final expression for the energy radiated by a perfectly black body in terms of temperature and wave-length becomes identical with that formerly given.

In a recent short publication of the Royal Observatory of Wilhelmshaven, the new director, Captain Capelle, explains how it is proposed to deal with arrears in the publication of magnetic work of that institution, and introduces a discussion of the magnetic character of the year 1910, by Prof. Bidlingmaier, who is now a member of his staff. Dr. Bidlingmaier regards the degree of disturbance of each individual hour as given by the numerals 0, 1, or 2, according to the extent of the departure of the corresponding portion of magnetic curve from the position characteristic of that hour on the average quiet day. The character of the hour is shown graphically by the colour of a small square, white, shaded, or black. The squares for adjacent hours and days are juxtaposed, so that the information is given for a whole month in a rectangular area about 80×65 mm., and that for a whole year in a couple of pages. Summing the numerical values for any specified number of hours, and taking the mean, a numerical measure is obtained for the average disturbance of the period, and certain conclusions are drawn as to the reality of 24-hour and 30-day disturbance periods. Whether the character of the hour is determined solely by reference to the horizontal force is not clear. A fuller explanation seems to be in view. The definition of disturbance presents a considerable resemblance to Sabine's, and whether it will commend itself to the general body of magneticians remains to be seen.

The Bulletins of the Cracow Academy of Sciences for 1910 contain three important papers by Prof. L. Bruner and his colleagues on photo-chemistry. The first action studied was that of light in promoting the conversion of maleic into fumaric acid in presence of bromine. In the absence of light, the bromine merely combines with the two acids to form dibromosuccinnic acids, the action proceeding fifteen times more quickly with maleic than with the more stable fumaric acid. In presence of light, perhaps because the bromination may become reversible, the main action is to cause the maleic to change into fumaric acid. This change, which is not effected in presence of chlorine or iodine or of the compounds ICl and ICl_3 was traced by measurements of conductivity and of solubility. The amount of fumaric acid finally produced depends on the nature of the light, but if this is fixed there is a definite ratio between the fumaric acid produced and the bromine used; by increasing the quantity of bromine, the maleic acid can be changed completely into fumaric acid. These observations reveal a striking contrast with catalytic

actions in which light is not concerned, since the concentration of the catalyst is then without influence on the final equilibrium between isomers. Other characteristics of photo-chemical action were shown by the investigation of the bromination of toluene under the influence of light. This action is extraordinarily sensitive to the presence of oxygen, which appears to give rise to oxidised bromine-compounds which carry on the action after the light has been removed; bromination in the side chain can, indeed, be effected almost violently *in the dark* if the material is subjected to the action of slightly ozonised oxygen, which thus acts as a most efficient "carrier" of bromine to the side chain. When these disturbing effects were got rid of by exclusion of oxygen and the addition of a little iodine, the velocity of bromination was found to be independent of the concentration of the bromine, *i.e.* equal quantities of bromine were used in equal times throughout the action. The action of various wave-lengths of light was determined with the help of a mercury lamp and light-filters, but all wave-lengths absorbed by the bromine appeared to take part equally in the photo-chemical action.

An account of a Garratt locomotive made by Messrs. Beyer, Peacock and Co., Ltd., of Manchester, for the Darjeeling-Himalayan Railway, appears in *The Engineer* for March 10. This railway is of 2 feet gauge, and presents peculiar difficulties on account of the steep ascent and frequent loops or spirals and reverses, one of the latter having gradients of 1 in 28. Curves of 70 feet radius are numerous. The specification for the locomotive included the condition that it should be able to travel over reverse curves of 60 feet radius with a length of tangent between the curves of 20 feet only. The engine consists of a girder frame, which is pivoted and supported at its extreme ends on four-wheeled bogies. Each bogie is a miniature locomotive *sans* boiler. The boiler supplying both is carried between the bogies on the girder frame. As there are no wheels under the boiler, the size of boiler is practically unrestricted. There are four cylinders each 11-inch diameter by 14-inch stroke, and fitted with Walschaert's valve gear.

Prof. Emil Fischer's lecture on "Neuere Erfolge und Probleme der Chemie," of which a translation appeared in Nature of February 23, has been published by the firm of Julius Springer, Berlin, price 0.80 mark.

OUR ASTRONOMICAL COLUMN.

The Spectrum and Orbit of o Persei.—In No. 10, vol. ii., of the Publications of the Allegheny Observatory, Mr. Frank C. Jordan discusses the spectrum and orbit of the spectroscopic binary o Persei. From a discussion of seventy plates, taken with the Mellon spectrograph during 1908–9, he finds that, instead of a radial velocity of -3 km., as found by Vogel, the centre of the system has a radial velocity of $+18.5$ km.; the orbit is practically circular, and the period is 4.4192 days.

The most striking fact educed by Mr. Jordan, however, is that the H and K lines of calcium do not appear to participate in the displacements due to motion in the line of sight shown by the other lines. In other words, whilst helium, hydrogen, magnesium, and carbon lines in the star's spectra indicate that the star is revolving in a circular orbit, the H and K lines indicate that the calcium vapour producing them is moving with a constant velocity away from us. Prof. Hartmann found the same phenomenon in the spectrum of δ Orionis, and, as the apparent velocity derived from the K line differed by 7 km. from the velocity of the centre of the system, he suggested that the calcium absorption took place in a medium lying between us and the star; such a suggestion is strengthened by the fact that most stars exhibiting this peculiarity lie in nebulous regions. But Mr. Jordan is inclined to question the difference of 7 km., which might be obviated by adopting other standard values for the wave-length of K, and, very tentatively, suggests that a clue to the phenomenon may be found in the fact that, of eleven stars exhibiting the peculiarity, ten are strong helium stars.

The Determination of Latitude.—While the Talcott-Horrebow method of determining latitude is the most important from the point of view of accuracy and facility of application, it generally necessitates the use of a specially constructed instrument, the zenith telescope. But in No. 4481 of the *Astronomische Nachrichten* Mr. Kiyofusa Sotome, of the Tokio Observatory, explains how the method may be used in connection with an ordinary field theodolite. Three wires, one vertical and two others 45° from the vertical, cross at the centre of the field of the telescope, and are carried by a reticle in the focal plane. Then a pair of stars are observed, circle east and circle west, and the time-intervals between the transits are noted. Knowing the declinations of the stars, Talcott's method gives the latitude, after the application of various corrections. Mr. Sotome explains the method in detail with formulæ, and shows that reasonable errors in the time intervals will not seriously vitiate the results. A series of seven observations at Tokio gave a mean error of $\pm 0.80''$, with a probable error of a single observation of $\pm 1.63''$.

The Relation between the Separation and the Magnitude of Visual Double Stars.—In No. 176 of the Lick Observatory Bulletins, Dr. R. G. Aitken analyses the degree of separation and the magnitudes of the double stars, brighter than magnitude 9.5 and closer than 5.0″, given in several large catalogues, and finds that the numbers of doubles consistently increase as one passes from the wider to the closer pairs. He also finds that the number of doubles of every distance-class under 5.0″ increases with increasing numerical magnitude; for instance, for B.D. stars as bright as magnitude 8.0 the proportion of doubles separated by less than 5.0″ is about 1 in $13\frac{1}{2}$, but for B.D. stars between magnitudes 8.0 and 9.0 the proportion is only 1 in 25.

Halley's Comet.—Already the periods of observation, both before and after perihelion, of Halley's comet, have easily exceeded those of any previous return; but observations are still being made at many observatories, and are likely to be continued for some time. M. Gonnessiat reports, in *Astronomische Nachrichten*, Nos. 4480–1, that on December 7 the magnitude was about 13.5, and that on February 25 it was 14.0.

In No. 4478 of the same journal Herr M. Ernst places on record his observations of the comet's magnitude on a number of dates extending from September 12, 1909, to June 30, 1910; his magnitudes for May 16 and 22, 1910, are -0.1 and -0.2 respectively.

The Path of Comet 1886 I.—More than one hundred columns of the *Astronomische Nachrichten*, Nos. 4477–8, are taken up by an exhaustive discussion, by Dr. Erich Redlich, of the available observations of the large comet 1886 I. After giving and discussing each observation in detail, Dr. Redlich derives a set of elements which give the eccentricity of the orbit as 1.0004461 ± 0.0000141.

Nova Lacertæ.—The faintness of this nova and the almost persistent cloudiness of our skies have prevented any extensive recent observations. In No. 4476 of the *Astronomische Nachrichten*, however, Prof. Millosevich reports that on February 10 the magnitude was 8.8.

Earthshine on the Moon.—To the casual observer of the heavens, the earthshine on the moon is deeply mysterious. On the evening of March 4, when our satellite was in conjunction with Saturn, the earthshine, as seen from Leeds, was unusually distinct, and many people, says Mr. J. H. Elgie in *The Yorkshire Post*, were led to believe that an eclipse was in progress. Mr. Elgie's observations showed that in the twilight the glow was of ashen hue, but that it deepened into olive as darkness came on.

Observations of Saturn.—On September 29, 1910, Signor Mentore Maggini, of the Ximénien Observatory, Florence, observed a bright projection on the limb of Saturn, and announced his observation in No. 4445 of the *Astronomische Nachrichten*. In the current number of *L'Astronomie* (March, p. 114) he gives further details, illustrated by an excellent plate drawing of the planet. He also describes various other phenomena observed during many nights of excellent seeing in September and October. Among others, he notes the dark equatorial band as double, the northern part being formed of oval spots, which at moments of good seeing gave the band the appearance of a chaplet. A difference of colour between the two annuli of this double band was also noted, the more southerly band having a greenish colour, the other being more of a reddish hue. The bright equatorial band, usually yellow, was often disturbed by greenish-grey shadings. Festoons, similar to those seen on Jupiter by Mr. Scriven Bolton, were frequently noted, seven of them being seen on September 30, 1910. Many other interesting phenomena appertaining to the rings, &c., are recorded by Signor Maggini.

THE GALTON BEQUEST.

Sir Francis Galton, F.R.S., who died on January 17, at the age of eighty-eight, has left the residuary estate under his will, amounting to about 45,000*l.*, to the University of London for the purpose of encouraging the study of national eugenics, which is defined in the will as the study of "the agencies under social control that may improve or impair the racial qualities of future generations, physically and mentally." Primarily, the object of the bequest is the establishment and endowment of a professorship in the University to be known as "The Galton Professorship of Eugenics," with a laboratory or office and library attached thereto; and the testator expresses a desire, without binding the Senate of the University, that the professorship shall be offered to Prof. Karl Pearson, F.R.S. The new professor will collect and discuss materials bearing on eugenics, form a central office to provide information to private individuals or public authorities concerning the laws of inheritance of man, and will urge the conclusions as to social conduct which follow from such laws. In addition, he will be required to extend the knowledge of his subject by teaching and research. The wish is expressed that the Senate will supply the laboratory or office, preferably, in the first instance, in proximity to the Biometric Laboratory, which is at present under Prof. Pearson's control at University College.

By this generous benefaction, permanent provision will be made for the work which has been carried on in the Francis Galton Laboratory in the University since October, 1904. This work was initiated by Sir Francis Galton, who supplied funds amounting to 3500*l.* during his lifetime for its support. Apart from the cost of printing the publications of the laboratory, nearly the whole of the money available has been devoted to the payment of the staff of the laboratory, including the emoluments of the Galton research fellow (Mr. David Heron) and the research scholar (Miss E. M. Elderton). A large number of lectures have been delivered in connection with the laboratory, and these have been well attended. The publications of the laboratory include "Noteworthy Families (Science)," by Galton and Schuster; a series of memoirs, of which fifteen have so far been published; a series entitled "Questions of the Day and of the Fray" (one publication); and a lecture series (six publications); in addition, the staff of the laboratory has published a number of papers in *Biometrika* and other periodicals. The subjects of the publications cover a wide range, including the principles of heredity, with special reference to insanity, vision, alcoholism, and various diseases and deformities. Some of the publications, notably those on alcoholism, have given rise to vigorous controversy. The laboratory has been fortunate in securing the cooperation of a large number of men of science and medical men.

The report on the laboratory published in the appendix to the second report of the Royal Commission on University Education in London (p. 399) indicates in a brief manner the ideas of those controlling its work as to future developments. The Solvay Institute at Brussels is mentioned as a possible model of what the Eugenics Laboratory should become; but for such a scheme a capital expenditure of 20,000*l.* and an annual income of 4000*l.* would, it is stated, be required, or an annual income of 5000*l.* if a sinking fund were established to repay capital expenditure in twenty years. The staff would then include a director (800*l.*), a trained actuary (600*l.*), medical officer (600*l.*), and six assistants (1200*l.*), the balance being used for library, publications, upkeep of buildings, and sinking fund. Those who have visited the Solvay Institute at Brussels will realise the great boon which such a scheme would confer on students of social questions in London. The arrangements made for private workers in the Brussels institute are as perfect as could be devised. Each worker has a private room, and the resources of the institute in books and information are placed entirely at his disposal. In close proximity to the institute for social workers at Brussels, are similar institutes for research in physiology and other sciences.

It may be of interest to note, in conclusion, the clear indication expressed in the will of Sir Francis Galton's desire that the work for which he has so generously provided shall have a direct bearing on practical life and on legislation. This side of the work has given rise to many misconceptions as to the character of the new science, which is popularly suspected of proposing artificial restrictions on the community in connection with marriage and child-birth. It may be said that there is little in the publications of the laboratory staff to support this view, though other exponents of the subject have expressed themselves with greater freedom and less regard, perhaps, to scientific data. As a good example of the way in which the new subject may affect legislation, Prof. Pearson's lecture entitled "The Problem of Practical Eugenics" may be mentioned, in which the effect of factory legislation on the birth-rate is explained in simple, non-technical language. The lecture provides at once an object-lesson for legislators and an admirable illustration of the use of statistics in the study of social questions.

T. Ll. H.

STANDARD TIME IN FRANCE.

At midnight on March 10 the clocks at the railway stations and all Government offices and municipal buildings of France and Algeria were set back nine minutes twenty-one seconds, to bring them in accord with Western European or Greenwich time, which will now be used in those countries, as it is in most other countries of Western Europe. The Paris meridian will, however, continue to be used as a standard for naval, astronomical, and cartographical purposes. A reform which has been urged in France for many years has thus at last been accomplished, and there can be no doubt as to the wisdom of the act, whether considered from the point of view of convenience or from that of international standards. It is not so much a question of the adoption of Greenwich time instead of Paris time as of France coming into a system of time-reckoning adopted by almost all the great countries of the world.

The zone-system of standard-time meridians separated by hours or half-hours, and encircling the globe, has undoubted advantages, and France occupied an anomalous position while it retained a time-standard having no simple relationship with the international system. The originator of this system was Sir Sandford Fleming, who, since he first suggested it in 1878, has done much to bring about the unification of time-reckoning throughout the world. Thanks to his persistent advocacy, twenty-four meridians are now recognised, beginning with that of Greenwich and counting towards the east. The time of each of these meridians is thus one hour behind that of the next meridian to the east of it, and one hour in advance of the next meridian to the west. Each meridian may be regarded as the median line of a zone 15° of longitude in width, so that the twenty-four meridians give standard-times on an organised system for the whole world. Local circumstances sometimes make it convenient to adopt the time of a meridian half-way between two of the twenty-four meridians, but this only means that the time will differ

from other times in the system by an odd half-hour as well as an exact number of hours.

The subjoined table, adapted from one in "Hazell's Annual," shows the standard meridians used by various countries, with which France has now come into line:—

Standard Times.

Greenwich Time..	Great Britain, Spain, Belgium, Holland
1h. fast on Greenwich	Italy, Austria-Hungary, Switzerland, Germany, Denmark, Norway, Sweden
2h. fast	Cape Colony, Transvaal, Orange River Colony, Natal, Turkey, Egypt
4h. ,, ...	Mauritius and dependencies (except Chagos) and Seychelles
5h. ,, ...	Chagos Archipelago
$5\frac{1}{2}$h. ,, ...	India
$6\frac{1}{2}$h. ,, ...	Burma
8h. ,, ...	West Australia, Coast of China from New-chwang to Swatow, up Yangtse to Hankow, Hong Kong, Labuan, British North Borneo
9h. ,, ...	Japan, Philippines
$9\frac{1}{2}$h. ,, ...	South Australia
10h. ,, ...	Victoria, Queensland, New South Wales, Tasmania
11h. ,, ...	New Zealand
1h. slow	Iceland
	America—
4h. ,, ...	Atlantic
5h. ,, ...	Eastern
6h. ,, ...	Central
7h. ,, ...	Mountain
8h. ,, ...	Pacific

Russia, Portugal, and Ireland still remain outside the system; but perhaps the example now set by France in sacrificing national sentiment to a scientific principle will induce these countries to link up their times with those of other nations by the adoption of convenient meridians simply related to those of the international standards.

A LONDON INSTITUTE OF TECHNICAL OPTICS.

A SCHEME for the establishment of an Institute of Technical Optics has now been approved by the Education Committee of the London County Council, and will shortly come before the Council. The object of this scheme is the establishment in London of an Institute of Technical Optics for the widest possible training of opticians and optical instrument makers, and it is also hoped that valuable work may be done in connection with investigations in optical glass, for which this country now so largely depends upon imported supplies.

The Education Committee proposes that the Council shall grant 35,000*l.* for the building and equipment of the new institute, the site, valued at about 12,000*l.*, having been already provided by the Northampton Polytechnic Institute, under the direction of the governors of which the new institute will be maintained. To ensure that the work shall be on the best lines, it is proposed to appoint a consultative committee representative of the trade, scientific, and other organisations interested.

The new institute will be maintained from funds at present used to maintain the Technical Optics Department of the Northampton Polytechnic Institute, additional grants from the Board of Education, and additional contributions from the London County Council. Later it is hoped that, in view of the national character of some of the work which may be developed, assistance may also be obtained from imperial funds.

In the proposals under consideration, provision is made for the teaching of optical science with its technical applications, and of other subjects of value to the manufacturer and designer of optical instruments, and to the optician.

Such instruction will be given in day and evening classes, the former being arranged to train men for positions as captains of industry in the trade, while the latter will be chiefly concerned with improving the technical and scientific equipment of those already engaged in the trade. In addition to the necessary auxiliary subjects, such as mathematics, drawing, elementary physics, &c., the courses would deal with (*a*) the theory of optics and optical systems, the design of optical systems, the methods of manufacture, and the testing of lenses and other optical work; (*b*) the principles, design, and construction of optical instruments (such as telescopes, microscopes, spectroscopes, photographic apparatus, surveying and other instruments, &c.), their adjustment, testing, and use; (*c*) the manufacture, testing, &c., of spectacle frames and lenses; (*d*) physiological optics.

In the various courses suitable laboratory and workshop classes will be included. The day courses will train men, some of whom may be recruited from the universities, as designers, test-room and general technical assistants, or as retail opticians, the evening classes in corresponding branches supplying theoretical and laboratory knowledge to men already engaged in the trade.

Day classes are also proposed for boys who intend to enter the optical trades as lens workers or instrument makers; these courses would take the place of part of the time of apprenticeship; they would probably be on the general lines of such courses held in connection with other trades. In addition, workshop classes, associated with elementary theoretical classes, would be provided for workmen desirous of becoming foremen or of improving their work in special directions. Facilities for research work on technical problems will also be provided, and students encouraged to pursue such investigations under the direction of a carefully selected and capable staff. Special investigations of questions of general interest to optical instrument makers, as, for instance, the questions connected with optical glass, will also be undertaken.

The above is a bare statement of the character of the proposed institute, and the funds which it is hoped will be available for its establishment and maintenance. Nothing has been said of the very strong arguments upon which the case for the founding of such an institute rests. These are embodied in two elaborate reports covering nearly forty pages of foolscap print, and signed, respectively, by the education officer (Mr. R. Blair) and the educational adviser (Dr. Garnett) of the London County Council. The wide reaching and important character of the work to be undertaken is very fully set out, and it is scarcely too much to say that these reports contain food for serious thought for every scientific worker in physical, chemical, and natural science.

THE STEREOCHEMISTRY OF NITROGEN.

AT the end of December, 1909, attention was directed in these columns (vol. lxxxii., p. 266) to the preparation by Profs. Perkin, Pope, and Wallach of an acid of the formula

$$\begin{matrix}H\\CH_3\end{matrix}\!>\!C\!<\!\begin{matrix}CH_2-CH_2\\CH_2-CH_2\end{matrix}\!>\!C\!=\!C\!<\!\begin{matrix}H\\COOH\end{matrix}$$

which contained no asymmetric atom, but which was capable of existing in two enantiomorphous forms—each having a large optical rotatory power—because the molecule, as a whole, was devoid of any plane of symmetry.

This important method of investigation has been extended to the stereochemistry of nitrogen by Dr. W. H. Mills and Miss Bain, whose observations are recorded in the Chemical Society's Journal. The substance investigated was the oxime of the formula

$$\begin{matrix}H\\HO.CO\end{matrix}\!>\!C\!<\!\begin{matrix}CH_2-CH_2\\CH_2-CH_2\end{matrix}\!>\!C\!=\!N.OH.$$

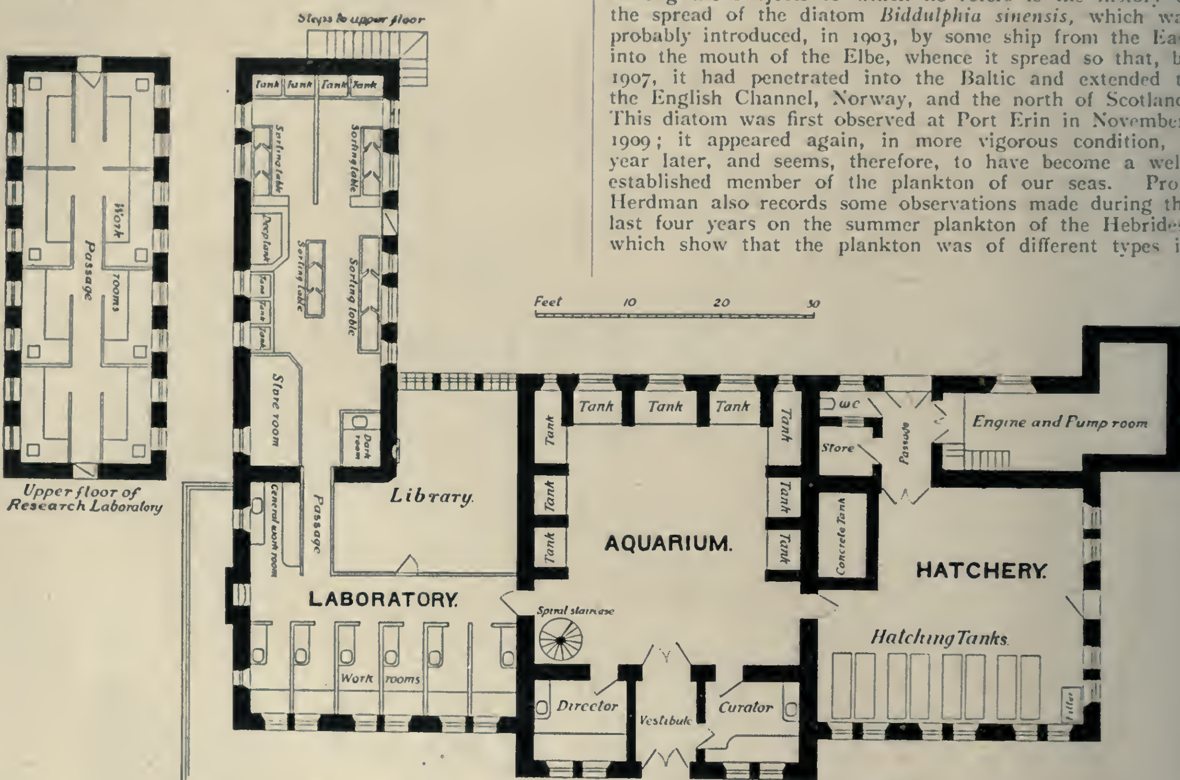
This oxime is obviously not symmetrical on either side of the plane of the ring, but would possess a plane of symmetry perpendicular to the ring if it could be assumed that the hydroxyl-group is situated in this median plane. The view that the hydroxyl-group is not situated in the plane of the remaining valencies of the nitrogen atom was advanced by Hantzsch and Werner in order to account for the isomerism of certain aromatic oximes, but was based upon somewhat slender evidence. In the case of the oxime formulated above, the matter can be tested directly by determining whether it can exist in optically active forms or not. The experiments show that the resolution of the oxime can actually be effected by means of morphine or quinine. It has a high rotatory power, not less than

$[M]_D \pm 91°$, but this is evanescent, the compound racemising rapidly and becoming inactive in the course of a few minutes or hours.

From its marked optical activity, it is clear that the oxime is asymmetrical in its structure; this probably applies both to the hydroxime $>C=NOH$ and to the isoxime $>C<\begin{smallmatrix} NH \\ | \\ O \end{smallmatrix}$ forms of the compound, but further work with derivatives of both types would be of great value in determining the range over which the lack of symmetry extends.

MARINE BIOLOGY AT PORT ERIN.

THE twenty-fourth annual report of the Liverpool Marine Biology Committee, dealing with the year's work of the Port Erin Marine Biological Station, affords ample evidence of the continued activities of this station. Details are given of the recently built research wing, the equipment of which is being pushed forward so as to be ready for use during the coming Easter vacation. This wing, 44 by 18 feet, two storeys high, contains on the ground floor a photographic dark-room, and a large and two smaller tank-rooms suitable for experimental work in biochemistry, comparative physiology, and embryology of marine animals. These three well-lighted rooms have cemented floors and walls, and are well provided with concrete tanks, of different sizes and depths, over which there are taps giving abundant supplies of sea water. Over a large central concrete platform, on which aquaria can be placed, will be a "plunger" apparatus for keeping in motion the water in the aquaria in which small animals are being reared. The upper floor contains eight separate rooms, each with about 13 feet of working bench, a sink, and supplies of fresh and sea water, which make an excellent addition to the accommodation available to research workers and senior students.



Plan of the Port Erin Biological Station, showing both Floors of the new Research Wing.

The report gives an account of the work done in the first course on oceanography, held at the station during August last. The usual work of the laboratory, in connection with research and the instruction of senior students, has been carried on; fifty-seven researchers and students have occupied the working places during the year. Mr. Riddell, who has been collecting the Polychaeta, reports the addition to the previous records for Port Erin of twenty-eight species. A note by Dr. Roaf, on his investigations on the secretion of the hypobranchial gland in *Purpura lapillus*, states that the purple-forming area of this gland is the site of formation of an adrenalin-like substance. The operations of the fish hatchery at the station have resulted in the liberation into the sea of more than eight millions of plaice larvæ and five thousand lobster larvæ.

The concluding portion of the report contains an account, by Prof. Herdman, of his plankton observations. Among the subjects to which he refers is the history of the spread of the diatom *Biddulphia sinensis*, which was probably introduced, in 1903, by some ship from the East into the mouth of the Elbe, whence it spread so that, by 1907, it had penetrated into the Baltic and extended to the English Channel, Norway, and the north of Scotland. This diatom was first observed at Port Erin in November, 1909; it appeared again, in more vigorous condition, a year later, and seems, therefore, to have become a well-established member of the plankton of our seas. Prof. Herdman also records some observations made during the last four years on the summer plankton of the Hebrides, which show that the plankton was of different types in different localities, but preserved a constant character in each; appended are some suggested explanations of the facts.

THE METHOD OF SCIENCE.[1]

SCIENCE governs human life by determining the conditions of existence and by furnishing the means of civilisation. Religion prescribes the motives, government formulates the customs of mankind, science fixes what we can do and how. If, at the present meeting, we appropriately emphasise the *rôle* of science, it does not imply that we belittle the ethical or social factors of civilised life, but answers the demand for a more just and general recognition of the actual importance of pure science.

We are so accustomed to the practical advantages that have followed from abstruse science, that we connect them

[1] From an address delivered by Prof. C. S. Minot as president of the Section of Physiology and Experimental Medicine of the American Association for the Advancement of Science, at Minneapolis, December 29, 1910.

with their source only by a distinct mental effort. The wonders of practical science have been recited so often that their reiteration has become tedious, and we no longer feel strongly impelled to felicitate mankind on the parlour match, the telephone, and the antitoxins, although we indulge at present in an unsubdued, excited anticipation of wonders to come, especially in the domain of medicine. Are we not all on the watch for the announcement of the cure for cancer, and vaguely for other new and astounding reliefs from disease? Such concentration of interest upon novel practical results is not wholly favourable to science.

It is true that a large amount of investigation is going on which aims to secure immediate practical results. In chemistry and medicine especially, the activity in the work of applied science is very great. This condition gives a powerful fresh reason for defending pure, abstruse science. Applied science always has been, is now, and probably always will be, distinctly subsidiary to pure science. The final justification of all scientific research is undoubtedly the power it creates for the use of mankind, but the power must be created before it can be used. A little study of the history of science should suffice to convince any reasonable mind that the command we possess to-day over nature is due to the labours of men who have almost invariably pursued knowledge with a pure devotion uncontaminated by any worship of usefulness. These devoted idealists have gathered the varied mighty harvests by which all men have profited, but the debt of gratitude to them is unpaid.

The pursuit of abstruse science needs to be encouraged. It is insufficiently esteemed. This doctrine ought to be emphasised on all suitable occasions, but especially before the section of experimental medicine. The people cry for relief from sickness, and their demand for prompt, useful discoveries is so urgent that there is danger in it, since it tempts medical investigators away from the fundamental inquiries, which, answered, will give great results, and seduces them to work exclusively at secondary problems, from the solution of which quicker, but smaller, results may be expected. Pure science is broad; it embraces all. Applied science is a congery of fragments, of isolated problems, which lack cohesion and are without any necessary connection with one another. It is easy to understand why students of applied science have seldom made great discoveries.

In fact, scientific knowledge will not be compelled. We have to take what knowledge we can get, and by no means can we get always what knowledge we want. Pure science adapts its undertakings to these rigid conditions, and works where the opportunity is best—not so applied science.

Compared with the growth of science, the shiftings of Governments are minor events. Until it is clearly realised that the gravest crime of the French Revolution was not the execution of the king, but the execution of Lavoisier, there is no right measure of values, for Lavoisier was one of the three or four greatest men France has produced.

Since pure science has been pre-eminent in the past, not only in furnishing useful knowledge, but also as a chief foundation of human progress, and is likely long to continue equally pre-eminent, it is well worth while to study the general principles by which original research is guided. No previous definite study of these principles is known to me, although I have searched not a little to find one. All that I have been able to discover are treatises on logic, the reading of which, most active investigators would, I fear, find tedious and unprofitable rather than helpful and inspiring.

It is my belief that the logical work of scientific men is usually well done, and is the part of their work which is least faulty. The difficulties and the majority of failures are due, it seems to me, to two chief causes, the first, inadequate determination of the premises, the second, exaggerated confidence in the conclusions. If I am right, the method of science is the result of the effort to get rid of these two causes of error.

We must recognise in starting that the expression "the method of science" means more than "logic," being far more comprehensive when rightly defined. We cannot alter the fundamental conditions of knowledge, for we are still unable to add new senses or improve the brain—although eugenics dreams of a future with such possibilities—nor can we change the nature of the phenomena. The same fundamental resources are available for daily life and for science. We must be clear in our minds on this point, in order to comprehend that the fundamental distinction of the scientific method is its accuracy. Such being the case, a broad examination of the method of science reduces itself to the study of the general principles of securing accuracy.

If you will examine frankly your own opinions and those of your acquaintance, you will, it may be presumed, quickly acknowledge that many, perhaps most, of the opinions are not of scientific accuracy. On the contrary, they are, to a large extent, mental habits and the result of the summation and averaging of impressions. We get along in ordinary life satisfactorily enough with opinions thus formed by summation. Most human opinions, even when they are merely imitative, originate in this way, and are correspondingly untrustworthy. If we seek to explain the fallibility of ordinary opinions and testimony, must we not attribute it to the absence of the detailed evidence and the consequent impossibility of verifying the testimony?

We are thus led to recognise the preservation of the evidence as the fundamental characteristic of scientific work, by which it differs radically from the practice of ordinary life. I venture, accordingly, to define the method of science as the art of making durable, trustworthy records of natural phenomena. The definition may seem at first narrow and insufficient, but I hope to convince you that it is so comprehensive as to be not only adequate, but also almost complete.

All science is constructed out of the personal knowledge of individual men. Science is merely the collated record of what single individuals have discovered. Accordingly, we must consider, first, the way in which the individual knowledges are recorded and collated. The process begins, of course, with the publications of the special scientific memoir in which the investigator records his original observations and makes known his conclusions.

It is interesting to note that our present standards for original memoirs have developed gradually. In Harvey's essay on the circulation of the blood, published in 1628, there are no precise data as to his observations. The author does not think it necessary to specify how he has laid bare the heart or how often he has repeated his observations. His descriptions of the beating heart are vividly realistic. He writes with conviction and authority. The reader is compelled to believe him. Harvey, however, does not provide information to facilitate repetition of his work—he offers little aid towards the verification of his results.

In a contemporary article we expect a presentation of all the data necessary to render subsequent verification by other observers possible. We further expect clear information as to the amount of material on which the observations were made, or the number of experiments on which the work is based. In other words, a modern investigator will hardly receive consideration for his researches unless he furnishes every aid he can to facilitate criticising and testing his results. This severe standard has been only gradually evolved, but is now stringently enforced in all departments of science, and is the response in our practice to our need of eliminating the purely personal factor. It would be advantageous if scientific authors, generally, viewed the obligation of providing for verification as an even more serious duty than it is esteemed at present. It might, indeed, be a wholesome practice to demand that every scientific article should contain a special section or paragraph on the means of verifying the result, for verification by *Fachgenossen* is second in importance only to discovery in the progress of science.

The conditions of scientific progress have changed greatly, though very gradually. Two hundred years ago the number of active investigators was small. This year there are at least ten thousand men of substantial ability carrying on original researches, consequently each theme is being worked at by several men, and the final outcome is the consequence of collaboration, which is none the less actual and effectual because it is unorganised, and is usually not formally designated as collaboration.

These conditions have rendered great men somewhat less

important than formerly. Science grows by the accretion of ideas. Now, a great man has, let us say, twelve new ideas, where a man of ability has one. If science gets twelve new ideas, it matters little whether they come from one man or from twelve. To a certain extent, numbers make a substitute for genius—but nothing probably will ever replace that type of great genius, to which we owe most, the man who has a great thought, which no one has ever conceived before.

The nineteenth century, in response to the new conditions which have arisen in its course, has added another new standard for scientific memoirs—they must include a conscientious consideration of recent and co-temporary related work. Now the second step in science-making, after recording the new original observations, so as to make them accessible to others, is the collation of these same observations into broad general results. The aim is to eliminate the personal factor and to impart the character of impersonal, absolute validity to the conclusions.

In addition to the original memoirs, science profits by a large number of publications, almost all of which are of modern, often of very recent, creation. Broadly speaking, their aim is to promote that collation which is begun in the original memoirs. Germany is the home of most of these undertakings, which are familiar to us under the names of "Jahresberichte," "Centralblätter," and "Ergebnisse."

We recognise in the present methods of recording and collating scientific discoveries many adaptations which are due, it seems to me, essentially to the mere increase in the number of workers. But though the methods are modified, the essential steps are the same: first, the record of the individual personal knowledge; secondly, the conversion of the personal knowledge by verification and collation into valid impersonal knowledge; thirdly, the systematic coordination and condensation of the conclusions.

A defect—perhaps the most serious defect of our education—arises from our failure to make our students appreciate vividly the fundamental fact that science is based on personal knowledge. Our students are allowed to graduate from college, for the most part, without any comprehension of this great truth. The best of them start forth with a high reverence for the library, the place of records, but quite unaware that a still higher reverence is due to those who, by being the first to observe unknown things, have founded the knowledge the records of which the library keeps.

The divergence between philosophy and science shows itself most conspicuously in the personal mental attitude which philosophy cherishes and science seeks to overcome. Philosophers still discuss philosophers and their systems, scientific men pursue impersonal knowledge with such ardour that they are apt to know little of the history of science.

The records which we have considered thus far are those which serve to make the discoveries of individuals available for others. So soon as the discoveries are properly collated and sufficiently verified, they become permanent parts of science. Many definitions of science have been given, and did time permit it might be profitable to quote some of them—but is it not sufficient to define science as *knowledge which has acquired impersonal validity?*

We must now attempt a general examination of the records, which are used primarily to help the original investigator, though often preserved to assist his successors. The simplest form of record is the preservation of the actual specimen. Scientific museums are essentially storehouses for such records. Most of them, to be sure, maintain public exhibitions, which interest, stimulate, and possibly instruct the public, but the precious part of their collections comprises the objects possessed, which have served for some original discovery. Scientific museums are very modern; nearly all those in America have been started within a few years.

The progress of science is marked by the advance in the art of making research records. We all admit, in other words, that the progress of science depends partly on the perfecting of old methods, but chiefly on the invention of new ones. Despite the enormous variety in their nature and aims, all our technical methods have this in common —that their real purpose is to yield us records. Our microscopes, spectroscopes, measuring instruments, and many another apparatus have indeed their primary scope in rendering possible observations which are impossible with our unaided senses. They enlarge our field of inquiry, and put precision within our reach. Yet their usefulness is conditioned upon their enabling us to make records which else would remain beyond our power. On the other hand, there is a still larger class of apparatus which are obviously designed to make records. What has been said concerning apparatus might be repeated concerning methods.

It is remarkable that the vast majority of methods and apparatus are contrived to furnish a visible result. Sight has long been acknowledged by science as the supreme sense. Perhaps the philosopher was right who asserted that nothing is really known until it is presented in a visible form. We biologists cannot deplore too frequently or too emphatically the great mathematical delusion by which men often of very great, if limited, ability, have been misled into becoming advocates of an erroneous conception of accuracy. Although I have expressed myself on the subject before, its importance justifies recurring to it. The delusion is that no science is accurate until its results can be expressed mathematically. The error comes from the assumption that mathematics can express complex relations. Unfortunately, mathematics have a very limited scope, and are based upon a few extremely rudimentary experiences which we make as very little children, and of which, probably, no adult has any recollection. The fact that from this basis men of genius have evolved wonderful methods of dealing with numerical relations should not blind us to another fact, namely, that the observational basis of mathematics is, psychologically speaking, very minute compared with the observational basis of even a single minor branch of biology. Moreover, mathematics can at the utmost deal with only a very few factors, and cannot give any comprehensive expression of the complex relations with which the biologist has to deal. While, therefore, here and there the mathematical methods may aid us, we need a kind and degree of accuracy of which mathematics is absolutely incapable. For our accuracy it is necessary often to have a number of data in their correct mutual relations presented to our consciousness at the same time, and this we accomplish by the visual image, which is far more efficient for this service than any other means of which we dispose. When we wish to understand a group of complex related details, such as an anatomical structure, we must see them, and if we cannot see them no accurate conception of the group can be formed.

With human minds constituted as they actually are, we cannot anticipate that there will ever be a mathematical expression for any organ or even a single cell, although formulæ will continue to be useful for dealing now and then with isolated details. Moreover, biologists have to do with variable relations, some of which, of course, can be put into mathematical form, but we find that even the simplest variations become clearer to us when presented graphically. The value to every student of science of the graphic method has been immense. Biologists can work to advantage with quantitative methods, we welcome the increasing use of measurements in biology, we welcome the English journal *Biometrika*, the organ of the measuring biologists—but none the less we refuse to accept the mathematical delusion that the goal of biology is to express its results in grams, metres, and seconds. Measurements furnish us with so-called "exact" records, but the aim of science goes beyond the accumulation of exact records to the attainment of accurate knowledge, and the accuracy of our knowledge depends chiefly on what we see. The practice of science conforms to this principle, the definite affirmation of which may prove of continuing advantage.

No class of records illustrates the value of sight in science more impressively than those made by instruments for registering the time factor. The kymographion invented by Carl Ludwig is the prototype of many apparatus. In them all, a succession of events, like heart beats, for example, together with marks showing the time, are so registered that they can be seen simultaneously, and thus readily compared. If no such apparatus were available, much of our most important scientific knowledge would

not exist. To deprive mankind of microscopes or telescopes would be hardly a more serious blow to science. We do not, of course, depend on our eyes for the notion of time—for the congenitally blind perceive time—but so soon as we wish to know accurately the relation of changing events to time intervals, we depend upon having them recorded in a visible form. It is the practical acknowledgment of the superiority of the eye as an agent to make clear the correlation of data.

Scientific men base their work upon a series of assumptions: first, that there is absolute truth, which includes everything we know or shall know; secondly, that we ourselves are included in this absolute truth; thirdly, that objective existence is real; fourthly, that our sensory perception of the objective is different from the reality. These conceptions constitute our fundamental maxims, and even when not definitely put in words they guide all sound scientific research. Metaphysicians find such maxims interestingly debatable; but science applies them unhesitatingly, and is satisfied because their application succeeds. Philosophy, ever a laggard and a follower after her swifter sister, has lately, and somewhat suddenly, termed the scientific habit of work pragmatism, and has taken up the discussion of it with delightful liveliness. Let us acknowledge the belated compliment and continue on our way.

The practical result of the four maxims has been that we further assume that all errors are of individual human origin, and that there are no objective errors. We make *all* the mistakes, nature makes none. To render the pursuit of new knowledge successful, our basic task is to eliminate error, or in other words to decide when we have sufficient proof. The elimination of error depends primarily upon insight into the sources of error, which, since methods of all sorts are employed, involves an intimate technical acquaintance with the methods, with just what they can show, with what they cannot show, and with the misleading results they may produce. In the laboratory training of a young scientific man, one chief endeavour must always be to familiarise him with the good and the bad of the special methods of his branch of science. Not until he thoroughly understands the character and extent of both the probable and the possible errors is he qualified to begin independent work. His understanding must comprise the three sources of observational error, namely, the variation of the phenomena, the imperfections of the methods, and the inaccuracy of the observer. The personal equation always exists, although it can be quantitatively stated only in a small minority of cases.

The history of science at large, the history of each branch of science, and the personal experience of every active investigator, all equally demonstrate that the greatest source of error is in our interpretations of the observations, and this difficulty depends, it seems to me, more than upon any other one factor; upon our unconquerable tendency to let our conclusions exceed the supporting power of the evidence. Since generalisation is the ultimate goal, we are too easily inveigled into assuming probabilities to be certainties, and into treating theories, and even hypotheses, as definite conclusions. Each generation of investigators in its turn spends much time killing off and burying older erroneous interpretations. The business is seldom accomplished by direct attack, for error perishes only in the light of truth, as micro-organisms are said to perish suddenly when struck by ultra-violet rays. Owing to the load of false theories, we work like a mental chain-gang, and are never unfettered. The handicap imposed by wrong hypotheses has always impeded the growth of science.

The multitude of such experiences, great and small, has gradually created among scientific men a special highly characteristic mental attitude. They regard the majority of the accumulated data and many of the inductions of science as correct. This is their estimate of the great body of information which, though personal in its origin, has been in the course of time so tested and verified that it is looked upon as established and secure. When Asellus in 1622 discovered the lymphatics, or so-called lacteals, of the mesentery, and demonstrated that they convey products of digestion from the intestine, his knowledge was his own, and at first his only. Since then the observations have been repeatedly verified, and of course extended, and all uncertainty has vanished from our minds. Similarly, in innumerable other cases reasonable impersonal certainty has been attained. Yet the investigator lives in an atmosphere of concentrated uncertainty, for he is convinced that at any time new data may turn up, and that all generalisations are likely to require modification. We might well adopt as our cry: Incredulity towards the known; open credulity towards the unknown.

We think of science as a vast series of approximations, and our task is constantly to render our approximations closer to absolute truth, the existence of which we take for granted. We use our approximations as best we may, treating them in large part and, at least for the time being, as if they were accurately true, yet meanwhile we remain alert to better them. This has long been the standard of scientific thought. It is the pragmatic attitude of mind, but its new name has not rendered it a novelty.

The pivot of all research is adequate proof. It would certainly aid science if some competent philosopher should make a study of the practice of investigators in the various branches of science sufficient to render clear the general principles by which investigators decide when a new observation or a new induction is sufficiently proven. If we follow the advance of research in any particular direction, we soon realise that there is a more or less definite standard of proof, which, though never clearly formulated, is none the less insisted upon, so that any paper which does not come up to this standard is subject to unfavourable criticism. Two elements of this standard we know, the first the elimination of the recognised sources of error, secondly, the repetition of the observations so that the constancy of the phenomenon is assured. We cannot do more than allude to this theme, which I must leave to the future and to a more competent mind to analyse and develop.

To sum up. The method of science is not special or peculiar to it, but only a perfected application of our human resources of observation and reflection—to use the words of von Baer, the greatest embryologist. To secure trustworthiness, the method of science is, first, to record everything with which it deals, the phenomena themselves and the inferences of the individual investigators, and to record both truly; secondly, to verify and correlate the personal knowledges until they acquire impersonal validity, which means, in other words, that the conclusion approximate so closely to the absolute truth that we can be safely and profitably guided by them. The method of science is no mystic process. On the contrary, it is as easily comprehended as it is infinitely difficult to use perfectly, and at its best the method supplies merely available approximations to the absolute.

We set science upon the throne of imagination, but we have crowned her with modesty, for she is at once the reality of human power and the personification of human fallibility.

THE CALORIC THEORY OF HEAT, AND CARNOT'S PRINCIPLE.[1]

THE caloric theory of heat as developed by Carnot in his famous "Reflexions on the Motive Power of Heat" (Paris, 1824) leads immediately to the correct solution of the relations between heat and motive power (energy or work) in all reversible processes, and appears to be in some respects preferable to the mechanical theory as a method of expression, because it emphasises more clearly the distinction, first clearly stated by Carnot, between reversible and irreversible transformations, and because it directly provides the natural measure of a quantity of heat as distinct from a quantity of thermal energy.

Carnot first introduced the method of the cyclical process in discussing the action of a heat engine, and showed that, in the ideal case, if there were no direct transference of heat between bodies at different temperatures, the transformations of heat and motive power in such a cycle were reversible. Assuming that it was impossible to

[1] Abstract of the presidential address delivered before the Physical Society on February 10 by Prof. H. L. Callendar, F.R.S.

imagine a heat engine capable of producing motive power perpetually without taking any heat from the boiler, he concluded that the quantity of motive power, W, produced from a given quantity of heat, Q, by means of a reversible engine, working between given temperature limits in a cyclical process, was the maximum obtainable, or that the efficiency must be independent of the agents employed, and must be a function of the temperature limits alone. He expressed this by the equation $W/Q=F(t)$, between finite limits o° and t° C., or by the equivalent equation $dW/dt=QF'(t)$ for a cycle of infinitesimal range, dt, at a temperature, t, where $F'(t)$ (generally known as Carnot's function) is the derived function of $F(t)$, and must be the same for all substances at the same temperature.

Applying the equation in this form to a gas obeying the law $pv=RT$, he showed that the heat absorbed in isothermal expansion from v_0 to v was given by the expression $Q=R\log_e(v/v_0)/F'(t)$, and that the difference of the specific heats at constant pressure and volume, given by the expression $S_p-S_v=R/TF'(t)$, must be independent of the pressure, and the same for equal volumes of all gases. These results were new, but were confirmed experimentally by Dulong five years later. Carnot showed, further, that if the ratio S_p/S_v was constant (as found by Gay Lussac and Welter, and assumed by Laplace and Poisson), both S_p and S_v must be independent of the pressure.

The results so far obtained by Carnot, including the description of his reversible cycle and the deduction of his fundamental principle, were independent of any assumption as to the nature of heat. Applying the assumption of the caloric theory, that the quantity of caloric required to change the state of a substance from (v_0, t_0) to (v, t) was the same by any reversible process, Carnot deduced that, if S_v was independent of the pressure, the function $F'(t)$ must be constant, $=A$. This assumes that heat is measured as caloric, and that temperature is measured on the scale of a gas, obeying the law $pv=RT$, and having S_v independent of the pressure, which is equivalent to the modern definition of a perfect gas. Putting $F'(t)=A$, he obtains for the work W produced from a quantity of caloric, Q, supplied at a temperature, T, in a cycle of finite range T to T_0, an expression equivalent to the following:—

$$W=AQ(T-T_0).$$

Carnot was unable to reconcile this solution with the imperfect experimental data available in his day, and particularly with the observation of Delaroche and Bérard, supported by Laplace's theory, that the specific heat of air, S_p, diminished with increase of pressure, which we know now, from the experiments of Regnault, to have been incorrect. He therefore made no serious attempt to apply the solution, and subsequent writers have apparently failed to observe that it is the correct final solution of the problem on the caloric theory. With our present knowledge, it is easy to see that this solution of Carnot's is also consistent with the mechanical theory, and contains implicitly all the relations of heat and work so far as they relate to reversible processes. The quantity, Q, of caloric remains constant in reversible expansion, such as is postulated by Carnot, when no heat is supplied. The work done is directly proportional to the temperature range $T-T_0$. The absolute motive power or equivalent work-value of a quantity of caloric, Q, supplied at a temperature, T, is the maximum work obtainable from a perfect gas (and therefore from any other substance whatever) when $T_0=0$, namely, AQT. The efficiency of the cycle with range T to T_0 is $W/AQT=(T-T_0)/T$. The external work done in the cycle is the difference of the work-values of the caloric supplied and rejected, a result which is readily extended to cycles of any form.

To complete Carnot's solution, it is necessary to inquire what happens to caloric in irreversible processes, such as friction, or the direct passage of heat from a hotter to a colder body. Carnot, as we see from his posthumous notes, had already, before his early death in 1832, arrived at the general conception of the conservation of motive power, and had planned experiments in which the motive power consumed in friction should be measured at the same time as the caloric generated. According to his theory, it would have been natural to assume that the motive power of the caloric generated at any temperature, namely, AQT, should be equal to the motive power consumed in friction. But he realised that further experimental evidence was necessary, which was first supplied by Joule.

A quantity of caloric is defined in Carnot's equation as measured by work done in a Carnot cycle per degree fall. The absolute unit of caloric, which may appropriately be called the *carnot*, is that quantity which is capable of doing one joule of work per degree fall. The mechanical equivalent of Q carnots at T abs. is QT joules. From Carnot's data, the work done in a cycle per gram of steam vaporised at 100° C. per degree fall is 0·611 kilogrammetres, or nearly 6 joules. The caloric of vaporisation is 6 carnots. Similarly, from Kelvin's data for the pressure required to lower the freezing point 1° C., the caloric of fusion of ice is 1·2 carnots. Since this definition is independent of calorimetric measurements, it may be employed in a calorimetric test, in which steam is condensed at 100° C. on one side of a conducting partition, while ice is melted at 0° C. on the other, to determine by direct experiment what happens when caloric falls irreversibly by conduction from 100° C. to 0° C. We know that for each gram of steam condensed, or for each 6 carnots supplied at 100° C., 540/79·5 grams of ice approximately would be melted, or 8·17 carnots of caloric would appear at 0° C. The quantity of caloric is increased in the proportion 373/273. The motive power of the caloric remains constant if no useful work is done. The increase of the quantity of caloric is the same as if the available motive power AQ(T−T) had been developed and converted into heat by friction at the lower temperature. Whenever motive power is wasted in friction, or "in the useless re-establishment of the equilibrium of caloric," a quantity of caloric equivalent to the wasted motive power is generated. The total quantity of caloric in an isolated system remains constant only if all the transformations are reversible, in which case the motive power developed exactly suffices to restore the initial state. In all other cases there is an increase of caloric. The old principle of the universal conservation of caloric, which is true only for reversible processes, must therefore be modified as follows:—"*The total quantity of caloric in any system cannot be diminished except by taking heat from it.*"

This principle, with various modifications to suit special cases (such as conditions of constant temperature, pressure, or volume), is immediately recognised as one of the most fruitful in modern thermodynamics. But it appeals more forcibly to the imagination of the student, if established, as roughly sketched above, by a direct investigation of the properties of Carnot's caloric.

The caloric theory is seen to be perfectly consistent with Carnot's principle and with the mechanical theory for all reversible processes. Caloric is the natural measure of a quantity of heat in accordance with Carnot's equation if we adopt the gas-scale of temperature. The only defect of the caloric theory lay in the tacit assumption, so easily rectified, that the ordinary calorimetric units were units of caloric. The quantity measured in an ordinary calorimetric experiment is the motive power or energy of the caloric, and not the caloric itself. If this had been realised in 1850, it would have been quite unnecessary to recast and revolutionise the entire theory of heat. Evolution might have proceeded along safer lines, with the retention of caloric, and the investigation of its properties, which are of such fundamental importance in all questions of equilibrium in physics.

Since Carnot's equation, $dW/dt=QF'(t)$, was adopted without material modification into the mechanical theory, and $QF'(t)$ remained simply a quantity of Carnot's caloric (though Q was measured in energy units and $F'(t)$ received the appropriate value J/T required to reduce energy units to caloric), it was inevitable that Carnot's caloric should make its reappearance sooner or later in the mechanical theory. It first reappears, disguised as a triple integral, in Kelvin's solution (*Phil. Mag.*, iv., p. 305, 1852) of the problem of finding the available work in an unequally heated body. The solution (as corrected later) is equivalent to the statement that the total quantity of caloric remains constant when the equalisation of temperature is effected reversibly. Caloric reappeared next as the

"thermodynamic function" of Rankine, and the "equivalence-value of a transformation" (Clausius, *Pogg. Ann.*, 93, p. 487, 1854). Finally, in 1865, when its importance was more fully recognised, Clausius (*Pogg. Ann.*, 125, p. 390) gave it the name of "entropy," and defined it as the integral of dQ/T. Such a definition appeals to the mathematician only. In justice to Carnot, it should be called caloric, and defined directly by his equation $W=AQ(T-T_0)$, which any schoolboy could understand. Even the mathematician would gain by thinking of caloric as a fluid, like electricity, capable of being generated by friction or other irreversible processes. Conduction of caloric is closely associated with the electrons, and the science of heat would gain, like the science of electricity, by attaching a more material conception to the true measure of a quantity of heat, as distinguished from a quantity of thermal energy.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—An exhibition of 50*l.* a year, tenable for two years, is offered by the governing body of Emmanuel College to an advanced student commencing residence at Cambridge as a member of Emmanuel College in October. The exhibition will be awarded at the beginning of October.

The Day Training College will be known in future by the title of "The Cambridge University Training College for Schoolmasters." This change is made to meet a suggestion from the Board of Education.

The subject selected for the Adams prize in 1912 is "The Theory of Radiation." The experimental scrutiny of the spectra of gaseous substances has amassed much knowledge, already expressed in semi-empirical formulæ, relating to the structure of spectra, whether composed of discrete lines or of bands, and also relating to the influence of various physical causes, such as the admixture of other substances, on the relative intensities of the lines. The nature of the magnetic influence on lines and bands which is exhibited in the Zeeman effect awaits closer investigation, and the classification of the lines of a spectrum which it suggests may afford further clues towards the assembling of those groups of lines which are possibly in some way components of one fundamental mode of vibration. A critical discussion of some of the problems of molecular dynamics which are associated with these phenomena is proposed. This discussion might proceed either from some hypothesis of structure of the molecules of matter, or from comparison, by way of analogy, with the properties of known types of vibrations. Questions relating to the constitution of natural radiant energy in statistical equilibrium might also come up for consideration. The prize is open to the competition of all persons who have at any time been admitted to a degree in this University. The essays must be sent to the Vice-Chancellor on or before the last day of December, 1912.

The first lists of candidates for the tripos examinations next term have just been issued. The numbers of names are as follows:—mathematical tripos, part i., 127, part ii., 53; classical tripos, part i., 108, part ii., 9; law tripos, part i., 60, part ii. and for LL.B. degree, 75; history tripos, part i., 129, part ii., 108; theological tripos, part i., 38, part ii., 17; natural sciences tripos, part i., 223, part ii., 44; mechanical sciences tripos, 46; moral sciences tripos, part i., 7, part ii., 1; mediæval and modern languages tripos, 55; Oriental languages tripos, 5; economics tripos, part i., 18, part ii., 16.

LONDON.—A revised syllabus in physics for the B.Sc. pass examination for internal students has been approved to come into force in 1912. Internal students will in future be required to satisfy the examiners in the practical as well as in the written part of an examination in a science subject.

Dr. A. D. Waller, F.R.S., has been appointed as a representative of the University on the governing body of the Imperial College of Science and Technology to fill the vacancy created by the resignation of the Right Hon. Sir Henry Roscoe, F.R.S.

A memorial from the Deptford Borough Council has been presented to the Senate asking that immediate steps be taken with a view to the establishment at Goldsmiths' College of a University College for South London with low fees, available for day and evening students.

The D.Sc. in geology has been granted to Arthur Wilmore, an external student, and the D.Sc. degree in chemistry has been granted to Arthur Clayton, an internal student of the Royal College of Science.

The second annual report of the Military Education Committee, which has been presented to the Senate, shows that the University contingent of Officers Training Corps has made good progress during the year. The strength on December 31, 1910, was 33 officers and 953 cadets, and an artillery unit armed with two 18-pounder field guns has been formed during the year. A list of eleven cadets who have proceeded to commissions in the Special Reserve, or Territorial Force, is included in the report.

A university studentship in physiology of the value of 50*l.* is open. Applications must be received by the principal on or before May 31.

OXFORD.—On March 7 Congregation took into consideration a further amendment to the "Faculties" statute, which would have had the effect of exempting the lectures given by professors and readers in the University from the control of their respective boards of faculty. The amendment was approved by several of the professors, but opposed by others, including Prof. Gotch, professor of physiology. On a division it was lost by 32 to 66. This will have the effect of giving power to the boards of faculty to exclude the lectures of professors and readers from the official list of lectures.

PROF. DAVID A. MOLITOR has resigned the chair of topographic and geodetic engineering at Cornell University, which he has held since 1908. He is returning to private engineering practice in the West.

THERE is about to be tried an interesting experiment in academic cooperation between North and South America. At the suggestion of the University of La Plata, Buenos Aires, Prof. W. J. Hussey is to spend six months of the year in the service of that University and six months at the University of Michigan, where he has occupied the chair of astronomy and held the directorship of the observatory since 1905.

WE learn from *Science* that the State appropriation for the Massachusetts Institute of Technology is to be increased. There is to be paid annually, for ten years, to the institute the sum of 20,000*l.*, from January 1, 1912, to be expended under the direction of the corporation for the general purposes of the institute; the institute will maintain forty free scholarships in addition to those maintained already. From the same source we find that Mr. Carnegie recently wrote to the trustees of the Carnegie Institute at Pittsburg that he is prepared to increase the endowment income 10,000*l.* or 20,000*l.* a year if it can be shown that any department is hampered from lack of funds. An old student, who wishes to remain anonymous, has given, our contemporary states, to Phillips Exeter Academy 3555*l.*, with which to complete the Wentworth mathematical fund of 10,000*l.*

THE Army Council has made a number of decisions regarding the regulations for admission to the Royal Military Academy and the Royal Military College, and those under which commissions in the Regular Army may be obtained through other channels of entry. The lower limit of age at which candidates are permitted to compete for admission to the Royal Military Academy will next November be reduced to 16½ years, and that at the Royal Military College will in June, 1912, be reduced from 17½ to 17 years. Eventually the upper limit of age for admission at both colleges will be 19 years. After March, 1912, no further examinations will be held by the Army Qualifying Board. The leaving certificate for Army purposes has been redefined, and for the future is to be a certificate which testifies to a certain standard of proficiency in the subjects stated, and is granted by certain bodies to candidates not less than 16 years of age who have attended a course of study at a school approved by the Army Council. For the future, a certain number of cadetships at the Royal Military College will be reserved each half-year for the nomination by the Army Council of

suitable candidates at recognised schools. To be recognised by the Council, a school must be inspected by an approved educational body and reported as fulfilling the necessary educational requirements, and maintain a contingent of the Officers Training Corps. A certain number of prize cadetships is to be awarded to successful competitors at each half-yearly examination for admission to the Royal Military Academy and Royal Military College with the view of encouraging a higher standard of education among candidates for commissions in the Army, and of reducing in the case of the better qualified candidates the expenses incurred.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, March 9.—Sir Archibald Geikie, K.C.B., president, in the chair.—Prof. P. V. **Bevan**: The absorption spectra of lithium and cæsium. This paper gives an account of the continuation of work done on the absorption spectra of vapours of the alkali metals. Difficulty was found in obtaining tubes which were not acted on by lithium vapour, and this difficulty was never completely surmounted. By the use, however, of considerable quantity of lithium in a steel tube, the absorption spectrum was obtained, and twenty-seven lines of the principal series were observed. The measurements for the whole series are given in the paper, the lines from the tenth to the twenty-seventh being new. The paper further gives measurements of wave-lengths for the similar lines for cæsium. The series has been extended to include twenty-four lines, and remeasurements were made, as there was pointed out by Prof. Hicks some probable errors in former determinations. The two series for lithium and cæsium are compared with the formulæ suggested by Hicks, and it is found that the agreement of calculated and observed wave-lengths is exceedingly good, a slight change in one of the constants for cæsium being indicated.—Prof. P. V. **Bevan**: Dispersion in vapours of the alkali metals. This paper gives an account of measurements of the dispersion in rubidium and sodium vapours. The work is of the same character as that on the dispersion in potassium vapour described in the Proceedings of the Royal Society, A, 84, 1910. Dispersion curves for the rubidium vapour were obtained for the region of wave-lengths 6000 to 3000. Anomalous dispersion effects were observable at the first eight members of the principal series lines. These lines being pairs, interesting curves are obtained for the second and third pairs. The relative values of the constants in the Maxwell-Sellmeier formula are obtained, and similar conclusions drawn from them, as in the case of the paper already referred to concerning the numbers of atoms taking part in the absorption of light. Measurements of wave-lengths of the lines of the principal series are given, and these are shown to be in good agreement with the values calculated from the Hicks modification of the Rydberg formula. Similar measurements were made in the case of sodium. In this case the effects are not so large or so easily obtainable as in the cases of rubidium and potassium. Measurements were also made to see if any temperature effect could be detected in the ratios of the constants of the dispersion formula. These go to show that the ratios m_1/m_2, m_2/m_3, &c., where m_1/m_2, &c., are the constants corresponding to the first, second, &c., lines of the principal series, increase with increase of temperature. This result is what might be expected if the absorbing atoms are ordinary atoms to which corpuscles become attached, more complex systems corresponding to higher members of the series of lines in the spectrum.—J. **Kendall**: The ionic solubility-product. Previous investigations upon the simultaneous solubility in water of two substances containing a common ion have been confined to those cases in which the substances examined have been of the same type—*i.e.* either both strong or both weak electrolytes. In each case the experimental results have been considered to be consistent with the hypothesis of a constant ionic solubility-product, although, even in dilute solutions, the agreement is only approximate. The primary object of this research was to test the applicability of the theory to substances of opposite types, one strong and one weak electrolyte. Preliminary experiments showed that here also small divergencies were obtained. Finally, a series of experiments on all the possible types of combination of two electrolytes was carried out, first with dilute and afterwards with more concentrated solutions, in order to ascertain the cause of these divergencies and their bearing upon the solidity of the theory. The results obtained show that the mutual solvent actions of the two substances play an important part in the equilibrium. The general rule appears to be that two substances chemically similar in character give results in excess of theoretical, while with two chemically dissimilar a diminution is observed. In dilute solutions all divergencies are small, but fundamental, and in certain cases the amount due to each of the two substances is calculated. In the more concentrated solutions, where the solvent effect is greater, the three possible types of solubility curves are obtained and discussed, and it is found that in all cases experimental divergencies from values indicated by the constant solubility-product hypothesis can be fully accounted for by this solvent effect of the substances upon each other.—Dr. W. H. **Eccles** and H. **Morris-Airey**: Note on the electrical waves occurring in nature. The occurrence of a lightning stroke must, in general, give rise to either a solitary electric wave or a train of electric waves which will be propagated from the centre of discharge to unknown distances. These vagrant waves join with other natural electric phenomena to cause disturbances—technically called "atmospherics"—in the receiving circuits of wireless telegraph stations. Among these other phenomena may be mentioned charged hail or rain striking the air-wires and earth-air currents. The present communication describes an endeavour to determine the proportion of atmospherics of distant origin. The plan of attack was as follows:—One of the authors in London and the other in Newcastle arranged receiving apparatus just as for the telephonic reception of signals, and simultaneously listened at prearranged times, for atmospherics. A hand record of the time and intensity of each strong atmospheric was made on paper ruled to represent ten seconds of time per inch. By arranging the periods of observation to include the midnight time signals from the Eiffel Tower or from Norddeich, the time records of the two observers could be accurately coordinated. The observers exchanged copies of their records, and counted the number of marks coinciding in time. The results tend to show that about 70 per cent. of the atmospherics audible at two stations 270 miles apart are due to vagrant waves propagated from electrical discharges that take place at (possibly) very great distances.—Prof. E. A. **Schäfer** and K. **Mackenzie**: The Action of animal extracts on milk secretion.

Linnean Society, March 2.—Dr. D. H. Scott, F.R.S., president, in the chair.—Dr. **Burr**: Dermaptera (earwigs) preserved in amber.—Miss Laura Roscoe **Thornely**: Report on the marine Polyzoa of the collection made by Mr. J. Stanley Gardiner, in the Indian Ocean, in H.M.S. *Sealark* during 1905.—W. M. **Tattersall**: The Mysidacea and Euphausiacea collected in the Indian Ocean during 1905.

Royal Anthropological Institute, March 7.—Prof. Gowland, F.R.S., in the chair.—Dr. **Duckworth**: Cave exploration at Gibraltar in September, 1910. The object of this research was to gain information on the spot as to the exact conditions in which prehistoric human remains occur on the Rock of Gibraltar. In addition to a general survey of the locality, two caves were explored. The first cave examined is in Forbes Quarry, whence the human cranium, so well known as the Gibraltar skull, was obtained in 1848. The cave in question proved very difficult to work, owing to the great density of ten successive stalagmite strata composing its floor. The latter was exposed over a considerable area, and at a depth of 4 feet 6 inches solid rock was always present. No animal remains could be detected. Since this excavation, Forbes Quarry has been almost completely filled, owing to the fall of many tons of rock from the heights above. The mouth of the cave is now hardly accessible. The second cave was at a considerable height (800 feet) above sea-level. The excavation yielded abundant evidence that it had been a resort of prehistoric man in the early Neolithic stage of culture. The conditions are best ex-

plained by describing them as a cave kitchen-midden. The evidence of human occupation includes the larger part of a human skeleton of the Cro. Magnon type, in addition to stone implements, sherds, and shell ornaments. The associated fauna is varied. To the list of such animals as have been recorded already, the following can now be added, viz.:—wolf, seal (Monachus), and almost certainly chamois, with certain birds and reptiles. Special attention was given to the identification of small mammalian bones with the view of ascertaining the presence or absence of Arctic rodent types; the latter were not identified. The author intends to seek further permission from the authorities to continue these researches at an early date.

Mathematical Society, March 9.—Dr. H. F. Baker, president, in the chair.—Prof. G. B. **Mathews**: The reduction and classification of binary cubic forms which have a negative determinant.—Major P. A. **Macmahon**: The theory of partitions.—Prof. A. E. H. **Love**: The theory of the transmission of earthquake waves.

CAMBRIDGE.

Philosophical Society, February 20.—Sir George Darwin, K.C.B., F.R.S., president, in the chair.—Prof. **Nuttall**: The adaptation of ticks to the habits of their host. A survey of the present knowledge of the structure and biology of the Ixodoidea. The views expressed may prove of practical use in the study of the Ixodidæ.—Dr. **Cobbett** and Dr. **Graham-Smith**: The entry of bacteria into the lungs. Experiments made by the authors showed that, if *B. prodigiosus* be placed in the mouths of very young guinea-pigs, these micro-organisms may be found in the lungs a few minutes afterwards. The authors believe that the results obtained give the true explanation of the appearance of tuberculosis in the lungs of animals fed with tubercle bacilli in many experiments, and that they invalidate conclusions which have been drawn from such experiments as to the usual path of infection in pulmonary tuberculosis.—F. **Ransom**: The action of caffeine on muscle.—W. E. **Dixon**: Toleration to nicotine. One form of toleration to chemical substances is associated with their destruction and oxidation; the tolerance to alcohol and morphine are examples. In the case of nicotine, it has been found that normal animal tissues have the power to destroy a small quantity of the alkaloid. The tissues of animals which have been rendered tolerant to nicotine destroy a considerably larger amount. There is evidence to show that the destruction of the nicotine is not due to a chemical combination with the tissues, but that, on the contrary, it is brought about by ferment action.—Dr. **Cow**: The action of pituitary extract and adrenalin on peripheral arteries. Employing the method of O. B. Meyer, adrenalin constricted the peripheral arteries with the exception of the intravisceral portion of the pulmonary, the coronary, and cerebral arteries. The coronary and cerebral vessels were dilated, and the intravisceral portion of the pulmonary was unaffected. Pituitrin produced dilatation of the splenic, hepatic, and gastric arteries except along the first 3 or 4 mm. after their origin from the cœliac axis, in which part constriction was produced.—W. M. **Scott**: The action of ultra-violet rays on blood sera. Experiments were described showing that exposure to ultra-violet light destroyed the protective properties of immune sera in greater measure than it diminished their anaphylactic toxicity, and was therefore not of practical value for serum therapeutics.—E. A. **Owen**: The scattering of X-rays. Experiments have been made on the distribution of scattered X-rays. With hard rays, the distribution on the incident and emergent sides of the radiator is found to be the same. With softer rays the intensity is greater on the emergent side. This dissymmetry increases with the softness of the primary beam. It is also found that the dissymmetry alters somewhat with the thickness of the radiator.

PARIS.

Academy of Sciences, March 6.—M. Armand Gautier in the chair.—The president announced the death of van 't Hoff, correspondant in the section of mechanics, and gave a brief summary of his chief researches.—Armand **Gautier** and Charles **Moureu**: The examination of a new thermal water, presented as a prototype of a modern physico-chemical study of a mineral water. The methods of estimation of small quantities of lithium, manganese, antimony, bromine, fluorine, rare gases, &c. In addition to the ordinary physical properties, measurements of electrical conductivity, ionisation, and radio-activity were made. The radio-active emanation and the radium in the state of salt were estimated separately. Traces of antimony and tin were recognised in the chemical examination, and new methods are given for the determination of traces of lithium and fluorine.—A. **Haller** and Edouard **Bauer**: The action of ethyl chlorocarbonate on the sodium derivatives of ketones prepared by means of sodium amide. Isopropylphenylketone was converted into its sodium derivative by treatment with the theoretical quantity of sodium amide in presence of benzene; the slow addition of ethyl chlorocarbonate resulted in the formation, not of ethyl benzoyldimethylacetate, but of its enolic isomer. Other ketones of different types furnished similar products.—A. **Lacroix**: The radio-active minerals of Madagascar. A general description of the nature of these minerals and the conditions under which they are found. A detailed account of their analysis and radio-activity is reserved for a later paper. Complete analyses are given for samples of bloomstrandite, euxenite, samarskite, and fergusonite.—Ch. **Bouchard**: The toxic theory of sleep. Remarks on a recent paper on this subject by MM. Legendre and H. Piéron. The author notes that he published analogous experiments in 1886.—Edouard **Heckel**: A new plant from Madagascar giving aniseed oil. From the specimens examined, the author concludes that this plant is probably *Pelea madagascarica*. The parts of the plant examined contain from 4 to 5 per cent. of the essential oil, and the results of a physical and chemical examination of the oil are given.—J. **Guillaume**: Observations of the sun made at the Observatory of Lyons during the fourth quarter of 1910. Observations were carried out on forty-seven days during the quarter. The results are given in tables showing the number of spots, their distribution in latitude, and the distribution of the faculæ in latitude.—Ch. **Galissot**: The selective absorption of the atmosphere. During 1909 and 1910 the author has repeated at the Observatory of Lyons the observations of Müller, using the Nordmann heterochrome photometer. Neither the observations of the author nor those of Müller can be represented on the usual hypothesis that the absorption depends only on the mass of air traversed.—Carl **Störmer**: The structure of the solar corona according to the Arrhenius theory.—D. **Eginitis**: Observations of the Faye-Cerulli comet made at the Observatory of Athens with the Gautier 50-cm. equatorial. Positions are given for December 3 and 23, and details of its appearance on those dates.—Robert **Jonckheere**: The discovery of new double stars at the Observatory of Hem.—Emile **Borel**: The structure of ensembles.—T. **Lalesco**: An integral equation of the Volterra type.—Louis **Roy**: The propagation of discontinuities in the motion of flexible wires.—J. **Paillet**, F. **Ducretet**, and E. **Roger**: A new method for the de-electrification of textile materials by means of high-frequency currents. Textile fibres during the processes of manufacture tend to become electrified. This causes separation of the fibres, leading to losses and deterioration of the product. The current methods of remedying this lead to the production of very moist and unhealthy atmospheres in the factory. The electrical method proposed by the authors is independent of the humidity and temperature, and gives better results in practice than can be obtained by the processes in ordinary use.—Pierre **Weiss**: An idea of Walther Ritz on band spectra. A discussion of some posthumous notes of Ritz.—F. **Leprince-Ringuet**: Formulæ relating to the transmission of heat between a fluid in motion and a metallic surface.—Ch. **Fery** and M. **Drecq**: The constant of radiation. A reply to some criticisms of MM. Bauer and Moulin on the method of calibration adopted in an earlier paper, and a description of a repetition of the experiments, with some modifications. The results completely confirm the determination published in 1909.—L. **Dunoyer**: The kinetic theory of gases and the realisation of a material radiation of thermal origin.—H. **Guilleminot**: The Sagnac radiations.—A. **Rosenstiehl**: Polymerised water and water of crystallisation. A reply to M. Lecocq de Boisbaudran.—J. **Boselli**: Reaction velocities in gas-liquid systems.—A. **Besson** and L. **Fournier**: The chlorobromides and

chloroiodides of silicon. The chlorobromides of silicon can be obtained in a pure state by the simultaneous action of hydrogen and bromine upon silicon tetrachloride under the influence of the silent discharge. The new method has the advantage of ensuring the absence of oxychlorides.—M. **Nanty**: The action of potassium bicarbonate upon magnesium chloride and upon soluble salts of magnesium in general.—G. **Darzens** and H. **Rost**: Some derivatives of butylcyclohexane. An account of the application of the Sabatier and Senderens method of adding hydrogen to butylphenol and its homologues.—André **Meyer**: The azo derivatives of phenylisoxazolone.—J. **Beauverie**: The hypothesis of the mycoplasma and the metachromatic corpuscles.—Pierre **Lesage**: The use of potash solutions for the recognition of the germinative faculty of certain seeds. It is shown that seeds that have lost their germinative faculty impart a colour to potash solution of a certain strength, whilst seeds still capable of germinating do not colour such solutions. As a means of rapidly sorting seeds, the author thinks this test may possess certain advantages.—Henry **Pénau**: The cytology of *Bacillus anthracis*.—A. **Marie** and Léon **MacAuliffe**: Anomalies in the dimensions of the ears in the insane.—L. **Spillmann** and L. **Bruntz**: The effect of certain pathological processes on the action of the leucocytes.—H. **Stassano** and L. **Lematte**: The possibility of preventing intact the agglutinated masses in bacteria which have been killed by the ultra-violet rays. The advantages of this means of sterilisation for the preparation of bacterial emulsions designed for sero-diagnostic purposes.—Pierre **Lesne**: The variations of feeding in the Coleoptera.—F. **Mesnil** and M. **Caullery**: Papillomatous neoformations in an annelid (*Potamilla torelli*). A description of a growth recalling the papilloma in vertebrates.—Edouard **Chatton**: *Paramyxa paradoxa*, a cnidosporidium without cnidoblast.—Carl **Renz**: The existence of some new Triassic deposits in central Greece.—P. and N. **Bonnet**: The existence of the Trias and the Mesojurassic in the *massif* of Kasan-Jalla (southern Transcaucasia).—L. **Cayeux**: The middle Miocene in the island of Crete.—Léon **Bertrand**: The structure of the western Pyrenees.—Louis **Fabry**: The three earthquakes of February 18 and 19, 1911. A discussion of the records of the seismograph of the Observatory of Marseilles.—The president gave an account of the legacy left by M. A. T. Loutreuil to the Academy of Sciences. This legacy amounts to 3,500,000 francs, and the testator's wishes as to the administration and application of the fund are given in full.

DIARY OF SOCIETIES.

THURSDAY, March 16.

Royal Society, at 4.30.—Gametogenesis of the Gallfly, *Neuroterus lenticularis*. Part II.: L. Doncaster.—The Action of the Venom of *Echis carinatus*: Sir T. R. Fraser, F.R.S., and Dr. J. A. Gunn.—Further Researches on the Development of *Trypanosoma gambiense* in *Glossina palpalis*: Colonel Sir D. Bruce, C.B., F.R.S., and others.—Spontaneous Cancer in Mice: Dr. M. Haaland.

Royal Institution, at 3.—Giants and Pygmies: Prof. A. Keith.

Linnean Society, at 8.—On the Brown Seaweeds of the Salt Marsh: Miss S. M. Baker.

Royal Society of Arts, at 4.30.—Education in India: C. H. A. Hill.

Institution of Mechanical Engineers, at 8.—Presidential Address: E. B. Ellington.

Royal Geographical Society, at 5.—Research Meeting. Names of the South Sea Islands: W. H. R. Rivers.—Geographical Monographs from Oxford. Salisbury District: L. M. Hardy.—Andover District: O. G. S. Crawford.

FRIDAY, March 17.

Royal Institution, at 9.—Water Supply: J. H. Balfour-Browne.

Institution of Civil Engineers, at 8.—The Production of Water-gas: Alwyne Meade.

SATURDAY, March 18.

Royal Institution, at 3.—Radiant Energy and Matter: Sir J. J. Thomson, F.R.S.

MONDAY, March 20.

Royal Society of Arts, at 8.—Applications of Electric Heating: Prof. J. A. Fleming, F.R.S.

Victoria Institute, at 4.30.—Prof. Hilprecht's newly-discovered Deluge Fragment: Dr. T. G. Pinches.

TUESDAY, March 21.

Royal Institution, at 3.—Explorations of Ancient Desert Sites in Central Asia: Dr. M. A. Stein.

Zoological Society, at 8.30.—On the Amphipod Genus Leptocheirus: Mrs. E. W. Sexton.—On Colour and Colour-pattern Inheritance in Pigeons: J. Lewis Bonhote and F. W. Smalley.—Notes on Marine Ostracoda from Madeira: Dr. G. Stewardson Brady, F.R.S.

Institution of Civil Engineers, at 8.—*Further discussion*: The Electrification of a Portion of the Suburban System of the London, Brighton and South Coast Railway: P. Dawson.

Royal Anthropological Society, at 8.15.—Physical Characters of Bushmen Past and Present: Dr. F. C. Shrubsall.

Royal Statistical Society, at 5.—Some Statistics of Japan: Charles V. Sale.

Mineralogical Society, at 5.30.—On Mr. Solly's Observation of Wiltshireite in 1903: Prof. W. J. Lewis, F.R.S.—Two New Minerals from the Binnenthal: R. H. Solly.—Notes on Cassiterite in the Malay Peninsula: J. B. Scrivenor.—Notes on the Occurrence of Dundasite in Derbyshire and Co. Galway, and of Bertrandite in Cornwall: A. Russell.—On Quartz-twinning: Dr. J. Drugman.—Crystallographic Notes: T. V. Barker.

WEDNESDAY, March 22.

Royal Society of Arts, at 8.—The Manufacture of Portland Cement: A. C. Davis.

Geological Society, at 8.—On some Mammalian Teeth from the Wealden of Hastings: Dr. A. Smith Woodward, F.R.S.—Some Observations on the Eastern Desert of Egypt; with Considerations bearing on the Origin of the British Trias: A. Wade.—Faunal Horizons in the Bristol Coalfield: H. Bolton.

THURSDAY, March 23.

THURSDAY, MARCH 23, 1911.

A CRITICISM OF THE DARWINIAN THEORY.

The Mutation Theory. Experiments and Observations on the Origin of Species in the Vegetable Kingdom. By Prof. H. de Vries. Translated by Prof. J. B. Farmer and A. D. Darbishire. Vol. ii., *The Origin of Varieties by Mutation.* Pp. viii + 683. (London: Kegan Paul and Co., Ltd., 1911.) Price 18*s.* net.

THE first volume of Prof. de Vries's great work was devoted in the main to an account of the results of the experimental cultivation of an *Œnothera* of uncertain origin, and of the conclusions he deduced from them. The second volume is more general in its scope, and is in effect a criticism of the Darwinian theory. The two might conveniently have been published in the reverse order. That, at any rate, will be found the best way to read them to get a clear idea of the author's point of view.

It is remarkable that pangenesis, the part of Darwin's theory which was received with least enthusiasm at the time of its publication, now almost overshadows all the rest. As Strasburger remarks:—

"Darwin's idea that invisible gemmules are the carriers of hereditary characters, and that they multiply by division, has been removed from the position of a provisional hypothesis to that of a well-founded theory."

De Vries thinks that the phenomena of variability and mutation follow deductively. And for this he claims the support of Darwin himself, who points out ("Variation," ii., 396), "on the hypothesis of pangenesis that variability depends on at least two distinct groups of causes":—(i) when the gemmules are unmodified, but deficient or superabundant, or are rearranged, or become active after being dormant; (ii) when they are modified through changed conditions. The former, Darwin thought, explained "much fluctuating variability"; the latter, the appearance of "new and changed structures." It is worth notice that Darwin uses here the word "mutation," but only apparently in the algebraic sense of permutations of the gemmules.

It is interesting to compare with Darwin's conclusion the form in which de Vries restates it in terms of his own views. I have inserted for clearness the corresponding numbers:—

"(i) Numerical changes of the pangenes are . . . the basis of fluctuating variability. Changes of the position of the pangene in the nucleus lead to the retrogressive and degressive mutations; (ii) whilst to account for progressive mutation we must assume the formation of new types of pangenes" (p. 645).

To de Vries, "fluctuating variability is a function of nutrition." It is also "linear, and oscillates only in a plus and minus direction." Mutation, on the other hand, "necessarily assumes a variability in all directions." It seems abundantly clear that "fluctuating variability" has by no means the same meaning to Darwin and to de Vries. It must be explained that in retrogressive mutation, characters become latent; in degressive, latent characters become active (p. 72).[1] De Vries states (p. 56) that

"one of the chief objects of the book is to show that ordinary or fluctuating variability does not provide material for the origin of new species."

But if it is merely a case of an individual organism being a little better or a little less nourished, I do not know that I should disagree. Darwin, however, would certainly not have agreed that ordinary variability was linear, or that, seeing he traced its cause to "changes of any kind in the conditions of life," that it was dependent exclusively on nutrition. The conditions throughout a population can never be so uniform that some amount of fluctuating variability is not excited. But if they are constant on the average, there is no resultant selective action. Thus the flora of Egypt has remained stable since at least the date of the Trojan war.

De Vries is extremely anxious to make Darwin responsible for the mutation theory. "It was Darwin who first attempted in various cases to distinguish between" mutability and variability. It is quite true that Darwin distinguished between the multiplication or reshuffling of his pangenes and their modification. But there is no warrant for asserting that he thought the former played no part in the origin of species. He assumed that "variability of every kind is directly or indirectly caused by changed conditions of life" ("Variation," ii., 255). Without variation, "natural selection can do nothing." All that he conceded was that variation might have a considerable range. But he was far from rejecting the efficiency of fluctuating variability. "Under the term 'variations' it must never be forgotten that mere individual differences are included" ("Origin," sixth edition, p. 64); "natural selection is daily and hourly scrutinising, throughout the world, the slightest variations" (*l.c.*, p. 65).

Another misconception, for which, however, de Vries is not responsible, is that Darwin's theory of pangenesis ultimately led him to a modified acceptance of Lamarckism, *i.e.* that new structures might arise in direct response to the environment. De Vries himself would not accept this. In Darwin's view, the modified pangenes would simply supply material for more ample variation, but natural selection would still determine the result.

De Vries is convinced, nevertheless, that Darwin was at heart a mutationist, and that his belief in discontinuous variability "under Wallace's influence gradually shifted into the background." There seems here to be a double misconception, which it is not difficult to clear up. Darwin, writing to Wallace in 1869, said:—

"I always thought individual differences more important than single variations, but now I have come to the conclusion that they are of paramount importance, and in this I believe I agree with you" ("Life and Letters," iii., p. 107).

It is clear that by individual differences he means fluctuating variability. He was preparing at the time

[1] This seems explicitly stated; I cannot reconcile it, however, with the equally explicit statement on p. 576, where the meanings of progressive and degressive appear to be interchanged.

E

the fifth edition of the "Origin," and in this there appears a passage of which it is sufficient to quote the first sentence:—

"It may be doubted whether sudden and great deviations of structure, such as we occasionally see in our domestic productions, more especially with plants, are ever permanently propagated in a state of nature" (p. 49).

But, as explained on p. 104, it was Fleeming Jenkin, and not Wallace, who led him to minimise the importance of "single variations, whether slight or strongly marked"; and as these are mutations, Fleeming Jenkin's argument cuts to the root of de Vries's theory.

But the real divergence between Darwin and de Vries is not so much as regards variability, but selection, the importance of which the latter consistently minimises. To Darwin, variability of any kind merely supplied the field in which selection works, and "sinks to quite a subordinate position in comparison." With de Vries it is exactly the opposite. "Specific characters do not arise by selection." The combinations of characters which arise from sexual reproduction are, however, subject to it. With respect to adaptations, which is the crucial point, de Vries speaks with a more uncertain voice than in his "Plant Breeding." "Everything points to the conclusion" that mutation "will explain adaptations just as completely, or, rather, just as incompletely," as natural selection acting on fluctuating variability. This is a cryptic utterance at best. But if natural selection cannot produce specific characters, it cannot endow them, except at haphazard, with survival-value; in that case, its inability to account for adaptations seems a necessary consequence. He finally sums up his position:—

"I willingly admit that almost anything can be squared with the theory in a very plausible way; . . . but this is not science."

Some of us think that it is, and there we must leave it.

De Vries has devoted immense labour to the investigation of the cases, not infrequent, where seedlings occur with more than two cotyledons. Two is a reduced whorl, and a whorl may be explained as due to the suppression of internodes. The number of leaves in a whorl is often variable, though seldom so in the case of opposite leaves; this is in accordance with the principles of the "repetition of similar parts." That two cotyledons should be the rule may well be adaptive, seeing that they have to be packed in the seed. That there should occasionally be more is a not improbable mutation. It is interesting to note that de Vries entirely failed to fix tricotyly by selection. Nor is tricotyly, although it appears to be not uncommon, often followed by trimerous leaves. De Vries has been more fortunate than I have been with the sycamore, as he raised two high trees with "branches in trimerous whorls." He says nothing about the leaves. I signally failed in raising a number of tricotyledonous seedlings; in the third year they all reverted to the opposite-leaved arrangement. And I have only come across a single case of the wild maple with trimerous leaves. This serves as an illustration, if one were wanted, of how little survival-value mutations possess in nature.

There can be no doubt that what we want is a purely empirical study of the variation under artificial but precise conditions of some clean-cut species free from any suspicion of hybrid origin. It would have to be done on a considerable scale, and as it would have to extend over a long period of years it would be a tedious and laborious business. I have some hopes that it may be undertaken in America. The horticultural papers are now full of what is taking place with *Primula obconica*, which from a condition of stability has passed into one of high variability. But, as de Vries very justly remarks, the available records in such cases "lack precision." But he arrives at the interesting conclusion that

"in horticulture . . . mutations are largely of the retrogressive or degressive kind. Discontinuous formation of species on the progressive line is much rarer" (p. 602).

Here species is used in the de Vriesian, not the Linnean, sense. The meaning, I take it, is that latent characters become active or the reverse. On an earlier page (p. 4) he seems to imply that all the cultivator can do is to evoke latent characters. "The first condition necessary for raising a novelty is to possess it."

Some fifteen years ago I made a careful study of what could be ascertained as to the cultural evolution of *Cyclamen latifolium*. I may state the conclusion, which I confess I was not prepared for:—

"The general tendency of a plant varying freely under artificial conditions seems to be atavistic, *i.e.* to shed adaptive modifications which have ceased to be useful, and either to revert to a more generalised type or to reproduce 'characters which are already general in other members of the same group.'"

As might have been expected, this had not escaped Darwin, from whom ("Origin," sixth edition., p. 127) I had quoted the concluding words of the sentence.

De Vries still maintains the singular distinction which he draws between cultural variation in horticulture and in agriculture; perhaps on the Continent the two arts are more distinct than with us, where it can hardly be maintained. "Horticultural varieties are generally constant" (p. 76). Agricultural races "remain dependent on continued selection, and do not really become constant" (p. 422).

The Darwinian theory rests on a number of converging lines of argument, and derives its probability from their cumulative force; just as in a law court each branch of evidence may be slender in itself, yet the conclusion to which they all point has a higher degree of probability than any one taken separately. De Vries's attack on natural selection, I must confess, would not shake my faith even if I found it more convincing than I do. But he is entitled to the merit, which he justly claims for himself, of having probed variability by a rigorous experimental method. It is much to be wished, but scarcely to be hoped, that others will follow him in his lifelong devotion to so laborious a research.

W. T. THISELTON-DYER.

MOVEMENT OF MOLECULES.

Brownian Movement and Molecular Reality. By Prof. M. Jean Perrin. Translated from the "Annales de Chimie et de Physique," 8me Series, September, 1909, by F. Soddy, F.R.S. Pp. 93. (London: Taylor and Francis, 1910.)

THIS small volume of ninety-three pages is a translation by Mr. F. Soddy, F.R.S., of a memoir published by Prof. J. Perrin in the *Annales de Chimie et de Physique* in September, 1909. In this paper, Prof. Perrin gave a detailed account of his work upon the distribution in fluids of small particles, which show the Brownian movement, and the bearing of these results on the kinetic theory of matter. An interesting survey is first given of the historical development of this subject. The English naturalist, Brown, directed attention in 1827 to the fact that small particles suspended in liquids were always in a state of rapid but irregular movement. Comparatively little notice was paid to this observation until 1889, when Gouy showed that the Brownian movement could not be ascribed to temperature differences, but was a persistent effect which was probably a necessary consequence of the kinetic theory of matter. Since that time a large amount of interesting work has been done, especially by Continental workers, to throw further light on the magnitude and nature of the Brownian movement.

After a brief account of the kinetic theory of matter and its application to the determination of the dimensions of atoms, Perrin gives a full description of his own experiments. Using an emulsion of gamboge and of mastic, he was able to determine the distribution in liquids of nearly equal granules, the diameter of which in different experiments varied between $0{\cdot}1\mu$ and μ ($\mu = 1/1000$ millimetre). By counting the number of granules at different levels by means of a high-power microscope, he found that the concentration of uniform granules decreased in an exponential manner with the height, in the same way as barometric pressure due to our atmosphere decreases with the altitude. The diameter of the granules was determined by direct weighing, and also by means of the formula of Stokes. From the data thus obtained, he has shown clearly that these granules distribute themselves exactly like a gas of very high molecular weight. It follows from this that each of these granules has the same kinetic energy of movement as a molecule of any gas or liquid at the same temperature. This is a very important deduction, for it shows that the law of equipartition of energy in all probability holds, not only for single molecules, but for granules containing many millions of molecules. From the experimental data, it is not difficult to deduce directly the numerical value of Avogadro's constant, *i.e.* the number of molecules in one cubic centimetre of any gas at standard pressure and temperature. The determination of this constant allows us at once to deduce the mass of any molecule, and also the value of the fundamental unit of charge carried by the hydrogen atom.

The experiments of Perrin are highly ingenious and interesting, and throw much further light on the behaviour of these granules. By examining some large granules of diameter, about 13μ which contained an inclusion visible in the microscope, he has been able to show that a particle, in addition to a slow Brownian movement, exhibits a spontaneous irregular rotation, and that the mean energy of this rotation is about equal to the mean energy of translation, thus establishing another deduction from the law of equipartition of energy.

In the last few years a number of methods have been developed for the determination of atomic constants, and a brief account of these is given at the end of the volume. It is of interest to compare the values obtained by Perrin with those obtained by other observers by entirely distinct methods. It is simplest to compare the results in terms of the value deduced for the charge e carried by a hydrogen atom. Perrin finds $e = 4{\cdot}1 \times 10^{-10}$ electrostatic units, while Rutherford and Geiger, from their counting experiments, found a value of $4{\cdot}65 \times 10^{-10}$. Recently Millikan, as a result of an admirable series of experiments on small drops of oil, has found a value equal to $4{\cdot}90 \times 10^{-10}$. In the course of his work, Perrin made special experiments in order to test the validity of the application of Stokes's formula for determining the diameter of a globule by its rate of fall, and concluded that it held accurately over the range of diameters of granules employed in his experiment. On the other hand, Millikan finds that Stokes's rule is not valid for small particles, and that the error becomes considerable for particles of diameter about 2μ, which is about the diameter of the granules used by Perrin in his most accurate series of experiments. The deviations from Stokes's law observed by Millikan are in general agreement with the conclusions recently deduced by Cunningham as a result of a mathematical investigation. If Millikan is correct, the size of the granules deduced by Stokes's method requires correction, and this would tend to bring the value of e found by Perrin in closer accord with that of Millikan. It seems possible, also, that the apparently large variations observed by Ehrenhaft in the value of the fundamental charge carried by very small particles, visible in the ultra-microscope and showing large Brownian movement, may be due to the failure of Stokes's formula for very small particles.

The questions discussed in this volume are of great interest and importance in molecular physics, and the reader cannot fail to be impressed by the remarkable advances which have been made in recent years in showing the validity and essential reality of the kinetic theory as an explanation of the properties of matter.

The work of translation is on the whole well done, and the vigorous style of the author is retained. The translation is in a few cases somewhat peculiar. For example, on p. 5, "Le mouvement brownien . . . persiste la nuit, *dans un sous-sol*, à la campagne," is translated, "The Brownian movement . . . persists equally, for example, at night on a *subsoil* in the country." Again, on p. 8, "nous *constatons* un équilibre" is given "we *establish* an equilibrium."

Mr. Soddy has done a valuable service in bringing to the attention of the general and scientific reader the very interesting and clearly written account of this subject given by Perrin.

E. R.

MEDICAL BIOLOGY.

Biology, General and Medical. By Prof. J. McFarland. Pp. 440. (Philadelphia and London: W. B. Saunders Co., 1910.) Price 7s. 6d. net.

PROF. McFARLAND tells us in his preface that "medical science is, in fact, a branch of biology, and should be studied as such." With this opinion we heartily agree, and we were fully prepared to find that the present volume would supply a long-felt want in demonstrating the importance of biological studies from the medical point of view. We still believe that the author has succeeded in doing this, but he has also succeeded in demonstrating the fact that a medical man is not always the most trustworthy authority on biological questions. The plan of the book is interesting, and, to some extent, original, commencing very appropriately with the cosmical relations of living matter and ending with a chapter on senescence, decadence, and death; and the author has successfully avoided the pitfalls of the type-system. Nevertheless, we can hardly share his somewhat curiously expressed hope "that the writing will not be found too technical to be beyond the comprehension of any intelligent reader."

The work is largely a compilation and is of a curiously mixed character, derived partly from text-books—some of a very elementary character—and partly from highly technical writings of a more or less controversial nature. For elementary zoological facts the author appears to have relied largely upon Masterman's "Elementary Text-book of Zoology," and Galloway's "First Course in Zoology," from which numerous illustrations are borrowed. The "New International Encyclopædia" has supplied a superfluity of information upon parasites, arranged zoologically, but we should be sorry to attribute responsibility for the author's statements to any of the works mentioned.

The theory of heredity is treated mainly by means of copious quotations from Herbert Spencer, Darwin, Galton, Weismann, and Adami. The amount of space devoted to the complicated lateral chain theory of the last-named author seems quite out of proportion to that given to other subjects.

We are obliged in justice to our readers to point out that the work contains numerous inaccuracies and misleading statements. Thus, for example, the shell of a tape-worm egg is described as a cell-wall; flagella and cilia are described as rigid protoplasmic threads; the shells of Foraminifera and Radiolaria are said to "find their homologues in the dermal coverings, the limbs, and fins, &c., of the higher animals"; the medusa of Obelia is said to have a water-vascular system, and so on. On p. 103 we are told that the germinal cells have twice the number of chromosomes possessed by the somatic cells, and our astonishment at this statement is only partially abated when we come to p. 189, and find that the author is referring to the doubling of the number of chromosomes which is supposed to take place in the maturation of the germ-cells prior to reduction, and fully realises that the actual gametes have only half the somatic number.

It is, perhaps, of no great consequence to the general reader or to the medical man if the sponges are defined as "characterised by many incurrent openings and only one excurrent opening. Axially symmetric. Sexually reproductive," but this diagnosis is so strikingly inadequate, and to some extent even incorrect, that it might just as well have been omitted, as might that of the arthropods, which are simply defined as "jointed animals." Moreover, it is always possible that the book may find its way into the hands of a student preparing for examination.

In the chapter on the origin of life the author suggests (or borrows the suggestion, it is not quite clear which) that the power of reproduction may be "only characteristic of such forms as shall have already evolved to a certain point." The possibility of organic evolution without reproduction is, we must confess, a new idea to us, and one upon which we do not think, with the author, that "it may not be unprofitable to speculate."

We can only hope that the more especially medical chapters, dealing with blood relationship, infection and immunity, will be found less open to criticism at the hands of medical readers.

A. D.

GEOLOGICAL ESSAYS.

Outlines of Geologic History, with especial reference to North America. A Series of Essays involving a Discussion on Geologic Correlation presented before Section E of the American Association for the Advancement of Science, in Baltimore, December, 1908. Symposium organised by B. Willis; compilation edited by R. D. Salisbury. Pp. viii+306. (Chicago: University of Chicago Press; London: Cambridge University Press, n.d.) Price 6s. net.

SOME of the best qualified geological writers and workers in America, including Dr. F. D. Adams from the Dominion of Canada, have here brought together their views on the correlation of stratified deposits. The series of essays was originally published in the *Journal of Geology*, and forms a text-book of North American stratigraphy, embodying results up to December, 1908. It is illustrated by Mr. Bailey Willis's "paleogeographic maps" of North America, which are a little difficult to read in their black and white shaded form. Our ignorance of what lies beneath the oceans probably gives a false impression of fixity to the continental boundaries in many cases.

The terminology used has been left to the various authors, so that we may welcome Mr. Willis's retention of "Cambrian" as against Mr. Grabau's "Cambric." Prof. Salisbury, as editor, points a warning finger towards Mr. Grabau's preferences on p. 44; but he is unable to save us from the "Beekmantownian" representative of the "Lower Ordovicic." Should not, by the by, the correct translation of the French "Plaisancien" be, not Prof. Osborn's "Plaisancian" (pp. 216 and 262), but either "Placentian" or "Piacenzan"?

We have the benefit of the views both of Dr. Adams and Prof. Van Hise as to pre-Cambrian classification. The former urges that the break between the Middle and Upper Huronian in America is at least

as important as that between the Keewatin and the Lower Huronian. Hence he is forced to oppose the division of the pre-Cambrian rocks into Archæan and Algonkian only. The early Palæozoic faunas fall naturally to the care of Dr. C. D. Walcott, who interestingly describes the oldest known Cambrian beds, those of south-western Nevada and eastern California (p. 31). In *Nevadia weeksi*, referred at first to Holmia, he recognises a form of trilobite "more primitive than such forms as *Olenellus thompsoni* (Hall) and *Holmia bröggeri* (Walcott.)" This phrase reminds us of the dangers that lie in wait for the palæontologist. Seeing that Olenellus was once regarded as expressing the decadence of the Paradoxides type, may not this suggestion of primitiveness arise from the fact that the Olenellus fauna occurs in California 5000 feet above these interesting strata?

Mr. Grabau carries on the correlation to "Devonic time," in a paper involving considerable labour. In Mr. Girty's essay on the Pennsylvanian, we notice (p. 125) one of the special points provided for us by America, viz., the occurrence of beds with *Productus giganteus* in California, which can be correlated more easily with the Carboniferous Limestone series of Europe than with the eastern Mississippian (Lower Carboniferous) series of America. Mr. Girty believes that none of the Upper Carboniferous faunas of North America are truly of fresh-water origin. Even the Appalachian facies (p. 128) with Naiadites, containing as it also does Lingula and "Aviculipecten," must at any rate imply brackish water.

It is hardly profitable to indicate isolated passages of interest in a book so full of condensed and well-ordered information. As examples, we may mention in conclusion Mr. White's sketch of the rise of the Devonian flora (p. 140), with its hint of Archæopteris prevalent in the upper series throughout the world; Mr. Williston's account of the faunal relations of early vertebrates; and Prof. Osborn's "correlation of the Cenozoic through its mammalian life." Though primarily intended for the specialist, these essays will do much to bring new life into the teaching and writing of British geologists who are willing to look beyond the seas. G. A. J. C.

THE ANALYSIS OF SYNTHETICAL DYES.

Tests for Coal-Tar Colours in Aniline Lakes: A Review of the Coal-Tar Colouring Matters generally used in the Lake Industry, and their Behaviour with Distinct Chemical Reagents. By G. Zerr. Authorised English edition by Dr. C. Mayer. Pp. xii+230. (London: C. Griffin and Co., Ltd., 1910.) Price 10s. 6d. net.

THE complex nature, as well as their ever-increasing number, render the analysis of synthetical dyes no easy matter. The work before us endeavours to fill a vacant gap in analytical literature, dealing as it does with the detection of a large number of these compounds in aniline lakes.

The book is divided into two parts.

Part i. takes account of the lakes which may be prepared from more than three hundred coal-tar colours. The author's experimental results obtained by a study of the action of selected chemical reagents (caustic soda, sulphuric acid, and stannous chloride in hydrochloric acid), and also of solvents (hot water, alcohol, and acetic acid) on these lakes, are arranged in columns, thus forming a series of tables, which comprise the greater part of the book. More than four hundred lakes are considered, and their behaviour towards sunlight, turpentine oil, and varnish is also mentioned in these lists.

Part ii. indicates the methods of recognising the various coal-tar colours in the lakes. Here also we have a number of tables which are really analytical schemes deduced from the results obtained in Part i., and containing sufficient details to explain their use. We have repeated some of the experiments mentioned in Part i. and have found them satisfactory. The author himself in Part ii. gives us three detailed examples of analysis, which may well serve as models in the investigation of lakes containing one or more colouring matters. The book will no doubt prove a trustworthy guide to those engaged in the analysis of lakes, and also to others who wish to enlarge their experience in the identification of synthetical dyes. Its utility, however, may be enhanced by the addition of a standard colour chart, which will more definitely explain column iv. of Part i., and by a supplementary column (in Part i.), which may include, whenever possible, the constitutional formulæ and systematic names of the various coal-tar colours mentioned by the author, together with any references relating to patents. The translator has done his part well, bringing the work up to date.

It is to be regretted that the translator, before issuing the book, had not worked out a similar table of tests for the coal-tar colours which are manufactured by English firms, as in its present form it distinctly tends to encourage the use of coal-tar colours made abroad as against those made by our own manufacturers.

DOMESTICATED ANIMALS.

Domestic Animals and Plants: A Brief Treatise upon the Origin and Development of Domesticated Races, with special Reference to the Methods of Improvement. By Prof. E. Davenport. Pp. xiv+321. (Boston, New York, Chicago, and London: Ginn and Co., n.d.) Price 5s. 6d.

THIS volume, we are told in the preface, is intended primarily for high and normal schools in the United States, and also appeals more specifically to the general student. Consequently, it is of the utmost importance that the information it contains should be thoroughly trustworthy. A survey of the sections devoted to groups of animals with which I happen to be more particularly acquainted shows, however, that this is very far, indeed, from being the case.

Take, for example, the statement on p. 96 that all the varieties of domesticated pigeons "have been bred within historic times from the single primitive form, the wild or passenger pigeon." That, in this astounding statement, the author has not by accident written passenger pigeon in place of blue rock, is manifest by the fact that a figure of the former bird is given on

p. 93, with a legend to the effect that it is the parent form. Apparently Prof. Davenport is unaware that the passenger pigeon belongs to a genus apart from the one including the blue rock and domesticated breeds.

The author's want of knowledge is, perhaps, still more conspicuous in the section on cattle and sheep (pp. 219–30), where blunders occur in profusion. In the legend to the figure of an Indian buffalo, on p. 218, we are told, for instance, that this is the only kind of buffalo, but that the name is often applied to the European (as well as to the American) bison. The gayal is stated on p. 221 to be "an intermediate between the domesticated and the wild cattle of the Indian type"; but even that statement is outdone on p. 223, where we are told that if the domesticated cattle of Africa and Asia were to die out, there would be no difficulty in replacing them from wild stocks! Where the author proposes to find a wild ox in Africa, I do not know; but he apparently does not realise the difference between a buffalo and an ox. After this it is not surprising to find the revival of the theory that white park cattle (which are stated to occur "at Chillingham in southern Scotland, and Chartley and Cadzow in southern England") represent the ancestral colour of the wild ox. Neither is it startling to find it stated (p. 228) that the Armenian wild sheep inhabits the islands of the Mediterranean, that the Cyprian wild sheep has more than two horns (p. 230), and that "the musk-ox stands between the cattle and the sheep" (p. 229).

With these and other blunders in a couple of sections, Prof. Davenport's volume can scarcely be recommended as a trustworthy guide to youth in search of information.

R. L.

POPULAR SCIENCE.

The Autobiography of an Electron; wherein the Scientific Ideas of the Present Time are explained in an Interesting and Novel Fashion. By C. R. Gibson. Pp. 216. (London: Seeley and Co., Ltd., 1911.) Price 3*s*. 6*d*. net.

A BOOK with so strange a title may well excite our curiosity, for it is not unnatural to expect in such an autobiography interesting speculations as to the nature and functions of electrons going beyond the limits of certain knowledge, and putting forward ideas suggestive of possible future advances in scientific thought. But though the electron is made to give an account of its experiences in different natural phenomena and experiments, it discreetly declines to tell us anything beyond what we know to be facts or what we are accustomed to regard as accepted physical theories. What, then, is the object of this story of the electron—or, more correctly, this series of stories about the experience of the electron in the different experiments described in each chapter? To use the author's own phrase, it is to present to his readers "a book which they may read with the same ease as an interesting novel."

Now it must be admitted that this desire to present to the scentifically untrained reader the established facts and theories of modern science, in a simple and pleasant form, is much to be commended; for the lack of interest taken by the general public in such matters is certainly deplorable. The author is right in thinking that there are many who would take an intelligent interest in scientific progress, but do not care to go into details, and no doubt men of science are largely at fault for not providing such readers with suitable literature. But it is difficult to see what is gained by the somewhat childish device of making the electron speak for itself, and describing the phenomena in the first person rather than in the more usual third person; besides, the contents of each chapter is preceded by a short synopsis called the "scribe's note," and the subsequent text takes one very little further than this note.

Although the particular form of the book seems to have no special advantage, the facts dealt with and their explanations are set forth quite clearly, and with accuracy, so far as is possible, in an elementary way; but there are disadvantages in the method of presentation which are worthy of mention. Whereas when dealing with certain fundamental conceptions of electricity it may be useful to introduce the idea of electrons, to do so seems to add nothing to the understanding of our methods of employing electricity for telegraphy, lighting, traction, and so forth. The principles involved in such technical application can be described without any reference to the ultimate nature of electric currents, without any sacrifice of precision; in fact, the consideration of the motion of the electrons only serves to detract attention from the more essential points. Again, the method of making the electron tell its own story leads the author into rather dogmatic statements on doubtful points. Thus it is found necessary to take up a definite attitude with regard to the nature of X-rays, which are described as æther-pulses, whereas of late considerable doubt has been thrown upon the validity of this conception of the radiation. Taken as a whole, however, this little book is quite a good and interesting popular account of some of the more important ideas of modern physics.

OUR BOOK SHELF.

Cat's Cradles from many Lands. By Kathleen Haddon. Pp. xvi+95. (London: Longmans, Green and Co., 1911.) Price 2*s*. 6*d*. net.

THE problem of the origin and diffusion of games is now generally recognised to be of some ethnographical importance, and Miss Haddon, in her careful account of the mysteries of cat's cradle, has done something to increase our knowledge. Like all pioneers in a new field of inquiry, she has to lament the scantiness of her material. Here and there persons interested in the subject have picked up various forms of the game among American Indians and Eskimo, the people of Central and South Africa, in the Caroline and Andaman Islands, in Oceania and Australia. But large regions, like India, from which only a couple of examples come, still remain practically unworked; and until the search for the game is more widely extended there will be no certain means of deciding whether it originated in one or many centres, and by what routes and agency it was diffused.

It is not surprising, as Miss Haddon remarks, that some of the plainer forms should have a wider dis-

tribution, because, given a simple loop of string, they would soon present themselves to the mind of the ingenious savage. But it is much more difficult to account for the presence of one of the most complicated forms in the Andaman Islands, Torres Straits, Australia, and Central Africa. In some cases doubtless this is the result of direct transmission, as when the puzzled folk-lorist finds "Cinderella" in the Cannibal Islands, he may reasonably suspect that she came with the Berlin-wool work and the hideous forms of dress popular in mission schools. But until more materials become available it is useless to speculate in this way.

This is some evidence, again, that certain forms of the game may be derived from magic of the sympathetic or mimetic kind; and inquirers interested in the subject would do well to ascertain if it is ever accompanied by magic formulæ or songs.

Meanwhile, Miss Haddon has given us a useful little book which may lead to the popularisation of the game in the kindergarten as a means of training eye and finger, or as a pleasant mode of wasting time for those who are no longer children.

A Course of Practical Physics. By Prof. E. P. Harrison. Pp. x+194. (London: Longmans, Green and Co., 1910.) Price 4*s.* 6*d.* net.

This book is based on the syllabus of practical physics for the B.Sc. degree of the University of Calcutta, and contains upwards of seventy experiments of an advanced nature. The author states in his preface that laboratory manuscripts have been used in its compilation, and this is far too evident in the result produced. Such instruction forms very often suffer from vagueness and looseness of expression, and although this may not be of much importance in the laboratory, where further explanations can be given by a demonstrator, yet in a published text-book care should be taken to eliminate such blemishes and make the descriptions more general and concise. To cite an example:—The determination of the thermal conductivity of copper on p. 130; the method is that of Searle; one is told to set up the apparatus as in the figure. The copper bar is not lagged, nor is there any mention in the text of the necessity of such lagging. Again, on p. 21—the determination of the period of vibration of a pendulum—it is not clear that the period needs correction (1) for size of amplitude, (2) for damping, but the corrections are merged into one causing ambiguity.

The author describes the measurement of galvanometer resistance on p. 156 (Thomson's method), and begins by telling us that one of 100 ohms resistance is convenient.

In some places the statements are inaccurate, *e.g.* on p. 175, the "neutral temperature" of a thermo-electric couple is defined as that temperature of the hot junction for which the electromotive force vanishes when the cold junction is maintained at 0° C. On p. 144, we have "Plot a B-H curve as in Fig. 101 (hysteresis loop shown). Determine the hysteresis in ergs per c.c. per cycle by measuring the area of the curve."

There is no doubt much in the book that will prove useful to students preparing for a pass degree examination, but its value would have been enhanced by the bestowal of more care in editing.

How to Colour Photographs and Lantern Slides by Aniline Dyes, Water and Oil Colours, Crystoleum, and other Processes. By R. Penlake. Pp. 77. (London: G. Routledge and Sons, Ltd.; Dawbarn and Ward, Ltd.; n.d.) Price 1*s.* net.

Although in the greater number of cases the less handwork there is on a photograph the better, it is often possible to apply colour to photographs and lantern slides in such a manner as not to interfere in any way with their value as impersonal records, and at the same time to increase considerably their value for demonstration purposes, and, in certain circumstances, to enhance their beauty. Experience has shown that the most suitable results are obtained by special methods, without the knowledge of which even the most skilful worker suffers a great disadvantage. It is the technicalities of these special methods that the author describes, dealing first with transparencies and colouring or tinting photographs on the face of them, and in the second part with the art of applying colours on their backs. He gives full instructions as to tools, colours, and processes without wasting any space in "artistic" platitudes.

Fables and Fairy Tales for Little Folk; or, Uncle Remus in Hausaland. By Mary and Newman Tremearne. First series. Pp. iv+135. (Cambridge: W. Heffer and Sons, Ltd.; London: Simpkin, Marshall and Co., Ltd., 1910.) Price 2*s.* 6*d.* net.

This is a popularised version of a series of folk-tales collected by Captain A. J. N. Tremearne, and published, with much useful information on the ethnology and customs of the Hausas, in the Proceedings of various societies. The tales add little to our knowledge of the manners of the people. Nearly all of them are based upon the theme of the transformation of men into animals and *vice-versa,* and there is little of the fairy element. The hero of many of the tales is Spider, who, like the fox of European and Chinese folk-lore and the jackal in India, is the type of the successful rogue. He is appointed king of the beasts, and in various ways swindles the elephant, rhinoceros, and hyæna. He marries a Hausa girl and has children, whom he shelters and dresses with his webs. His rival is the billy-goat, who plays tricks on the lion. In its present form, without notes or references from other folklore sources, the book is of little scientific value; but its quaint and humorous incidents of animal life will doubtless be fully appreciated in the nursery.

Early Britain. Roman Britain. By Edward Conybeare. Second edition, revised. Pp. 275. (London: Society for Promoting Christian Knowledge, 1911.) Price 3*s.* 6*d.*

This history of Britain, which extends to the year 455 A.D., begins with a treatment of the period shading on one hand into geology, and on the other into written history. The reader gets a glimpse of what the geologist has pieced together about the life of the inhabitants of this country in Palæolithic and Neolithic times, and an interesting account of the less ancient Britons. A very readable description is given of Britains under the Romans, in which the broad facts stand out clearly.

The Green Book of London Society. Edited by Douglas Sladen and W. Wigmore. Pp. xxii+524. (London: J. Whitaker and Sons, Ltd., 1911.)

This is the second issue of a comprehensive work of reference, the scope of which may be gathered from its sub-title:—"A Directory of the Court, of Society, and of the Political and Official World; including Celebrities in Art, Literature, Science, and Sport, with many other subjects of current interest." Science appears to be given about a page and a half, and the information includes a list of "eminent men of science who appear in London," the names of seven leading engineers, a list of twenty-four important scientific periodicals, and brief particulars of twenty-three scientific societies.

LETTERS TO THE EDITOR.

The Flow of Thin Liquid Films.

WHILST observing the "Brownian" movement of particles of gamboge in water with the aid of a microscope (magnification, about 360 diams.), it occurred to me to press gently on the cover-glass of the slide, so as to cause a movement of the water containing the suspended matter, and to note the paths of these in the vicinity of some larger stationary masses, as one would then be approaching the condition set forth by the late Sir G. G. Stokes, namely, that liquids in thin films behave as frictionless fluids. The results fully confirmed the behaviour of such thin films of liquid. The moving particles, as they rushed by the stationary masses, showed no trace of eddy currents, passing along the edges of the obstacle and leaving it without any swirls, as shown in Fig. 1. The moving particles next to the obstacle had a high velocity, and were in greater numbers per unit area, than those further removed; the obstacle had no effect upon distantly removed portions of the liquid—they moved in straight lines. For very low velocities the course of the particles was exceedingly in accordance with the motion of a frictionless fluid. With high velocities, a cone of slow-moving liquid formed both in front and behind the obstacle, as shown in Fig. 2. When two masses are in the same line of flow, it is difficult to prevent a certain number of particles, mapping out a stream-line, from crossing over from one side to the other between the obstacles, as shown in Fig. 3. We have here a hydrodynamical analogy to the circuit of a Wheatstone bridge

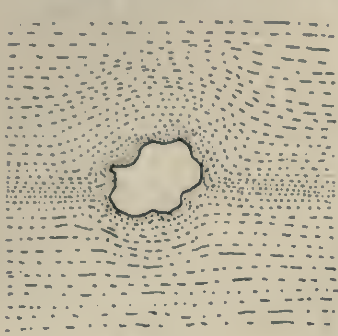

FIG. 1.

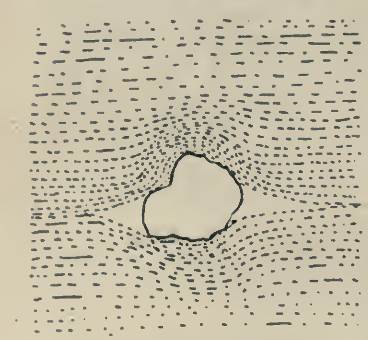

FIG. 2.

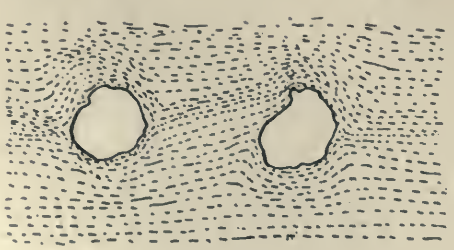

FIG. 3.

when determining the value of an unknown resistance. The liquid represents the metallic circuit, the particles of gamboge the current—or the corpuscles if preferred, the two obstacles the insulation between R_1, R_2 and R_3, R_4, and the fluid between them the galvanometer circuit. When equilibrium is established, no current flows through the galvanometer: no fluid passes across the intervening space between the two obstacles. Vary any one of the resistances, and equilibrium is upset, causing a current to flow through the galvanometer; cause an unbalanced pressure on one side or the other of the line joining the two obstacles, and a current of fluid flows from the place of greater to that of lesser pressure.

Very interesting effects are produced by introducing air bubbles into the liquid instead of solid obstacles. On pressing the cover-glass, the bubble appears to increase in size, while at the same time a rush of liquid passing it is noticed; on releasing the pressure, the bubble contracts, the liquid moving in the opposite direction. One of the most striking effects is seen when a bubble moves of its own accord through the liquid. The effect is difficult to produce, but well repays the effort. As before, gamboge is used to define the course of the surrounding fluid. As the bubble moves forward, the fluid next it is seen to be moving along its edge in the *same direction*, while at a little distance it is moving in the opposite direction to that in which the sphere moves. This effect is shown by the arrows in Fig. 4, the heavy arrow denoting the direction in which the sphere is moving: At the pole *c* the fluid seems to appear, passes with a high velocity to the pole *d via* the surface of the bubble, and disappears. The effect of the moving bubble on the surrounding liquid extends for a great distance compared with the case when the liquid is in motion and the obstacle stationary (*vide* ante).

Water-Vapour on Mars.

I NOTE in NATURE of February 9 (p. 486) an account of a recent unsuccessful attempt to verify the existence of water-vapour on Mars, already demonstrated by means of other methods by Dr. Slipher and myself (see *The Astrophysical Journal*, vol. xxviii., p. 397, December, 1908, and Lowell Observatory Bulletins, Nos. 36, 43, and 49). Will you allow me to point out that the method employed by Director Campbell was proposed several years ago by Dr. Percival Lowell, and was actually tested by Dr. Slipher at the Lowell Observatory in 1905, with a result similar to that which Director Campbell has now obtained in his repetition of the experiment? The details may be found in Lowell Observatory Bulletin No. 17.

The reason for the failure perhaps lies in the insensitiveness of the method. The spectrum of a body no brighter than Mars cannot be obtained with the utmost fineness of detail under a high dispersion, because a relatively wide slit has to be used, or else a very long exposure must be given to the photographic plate, either of which is fatal to sharp definition of fine spectral lines. In these circumstances it is not easy to distinguish between the terrestrial and planetary components of a fine absorption line with the high dispersion which is absolutely necessary to the success of the experiment.

It still seems to me that the best method of measuring the Martian aqueous vapour which is at present available consists in the observation of the little *a* band with a spectrograph of low dispersion, which gives the band as a shading in which individual lines cannot be discriminated, but the integrated intensity of which can be measured photometrically. The method is also applicable to those diffuse bands discovered by Abney and Festing in nearly saturated aqueous vapour, which apparently are not composed of fine lines, but which are sometimes much more intense than the linear groups.

Astrophysical Observatory, Westwood, Massachusetts, March 6.

The Fox and the Fleas.

I HAVE just been told a very interesting story by Mr. James Day of this town. Many years ago he and his father, both then engaged in agriculture, were sitting with their backs to the straw-covered hurdles which had

been put up to protect some sheep and lambs from the wind, when they noticed a fox come searching along the hedgerows. They kept perfectly still and watched, and, when he got nearer, they saw that he was collecting the sheep's wool caught on the thorns and brambles. When he had gathered a large bunch he went down to a pool at the junction of two streams, and, turning round, backed slowly brush first into the water, until he was all submerged except his nose and the bunch of wool, which he held in his mouth. He remained thus for a short time, and then let go of the wool, which floated away; then he came out, shook himself, and ran off.

Much astonished at this strange proceeding, they took a shepherd's crook, went down to the water's edge, and pulled the wool out. They found that it was full of fleas, which, to save themselves from drowning, had crept up and up the fox's brush and body and head and into the wool, and that thus the wily fox had got rid of them.

Cambridge, March 20. T. MCKENNY HUGHES.

THE CIRCULATION OF AIR IN THE SOUTHERN HEMISPHERE.[1]

IN this investigation of the circulation of the atmosphere in the southern hemisphere, the author has taken a new course. Instead of proceeding in the usual way from tables of wind-direction and force, he has taken as the groundwork of his researches the atmospheric whirls themselves. He does not deal with cyclonic systems, as one might at first suppose, but with the anticyclonic, the travelling high-pressure systems. The reason of this is plainly due to his previous work, "A Discussion of Australian Meteorology" (London, 1909). After a four-year period in the variations of air-pressure over India, South Africa, and South America, and their relations to the four-year cycle in the solar variations had been successfully demonstrated, it was necessary to investigate the weather conditions in Australia with that object. In the subtropical continents of the southern hemisphere weather conditions are chiefly influenced by barometric maxima almost constantly travelling from west to east. This was first shown to be so for Australia by the astronomer H. C. Russell, of Sydney, to whom the meteorology of that continent is so much indebted.

Russell already held the opinion that these travelling barometric maxima (with the V-shaped depressions accompanying them on their south side) do not originate on the continent itself, but approach from the South Indian Ocean. In Dr. Lockyer's extensive work, above quoted, it was shown more conclusively that in the Australian area, in latitudes 20° to 40° S., anticyclonic systems travel with great velocity from west to east, and that this also holds good for South America, South Africa, and Mauritius, in the same belt of latitude. In all probability, what holds good for 130° of longitude would also obtain for the rest of the earth's circumference. A proof of this would be of great importance for the weather prediction of these southern continents. The inquiry was therefore extended over the whole southern hemisphere, in order to obtain at the same time a more secure basis for the determination of the effects of the solar variations on the circulation of the air of the southern hemisphere.

The collection of the materials for this widely extended investigation naturally gave the author much trouble and difficulty. The determination of the amplitudes of the waves of atmospheric pressure over the whole of the district in question formed the preliminary part of the work in view. The author rightly confined himself to the southern winter half-year (April to September). It is quite clear that in calculating the mean height of the pressure waves, all waves, including even the smallest, cannot be taken into account, but only those of a certain magnitude. The author finds the amplitude of the pressure wave (Schwellenwerth) for these by selecting the three greatest wave heights for each station and takes one-fifth of the mean as the lower limit. This value (Schwellenwerth) is naturally different for different places in the various latitudes.

Dr. Lockyer calculates in this way the mean heights of the waves of air-pressure for fifty-five places in the southern hemisphere, between the equator and the Antarctic continent, and enters the values in the chart. That leads further to the drawing of lines of equal wave heights of oscillations of air-pressure. The author denotes these lines by the somewhat mysteriously sounding Greek compound "Isanakatabars": lines of equal up and down movements of air-pressure. The mean amplitudes of the waves of air-pressure naturally increase from the tropics towards higher latitudes. In latitude 0° to 12° S. they reach 1 to 2 mm.; from 12° S. they increase very rapidly and attain a maximum of 18 to 19 mm. in 53° to 60° S., and then decrease again to 14 to 15 mm. in South Victoria Land. The Isanakatabar of 16 mm. occasionally fringes the Antarctic continent. The increase of the wave heights towards the south is explained by the fact that from the belt of the travelling barometric maxima, with still relatively small amplitudes, we first enter the region of V-shaped depressions which accompany them, and then, finally, that of the large cyclones of higher latitudes, the mean tracks of which may probably be taken as between 55° and 60° S. At the southern limit of these, towards the permanent Antarctic anticyclone, the amplitudes again decrease. But, generally speaking, the Isanakatabars run fairly parallel to the parallels of latitude. They exhibit, however, the peculiarity that on the mountain ranges of the west sides of South Africa and South America they trend downwards in higher latitudes, but leave the east coasts in lower latitudes. This may be ascribed to the westerly ranges of mountains in these continents.

These Isanakatabars form the starting point of further very interesting deductions by the author.

It may here be remarked that Kämtz, in his "Lehrbuch der Meteorologie" (vol. ii., p. 339), has endeavoured to draw lines of equal non-periodical oscillations of air-pressure. He calculated for numerous stations of the northern hemisphere the mean value of the *monthly variation* of air-pressure, and called his lines based thereon somewhat improperly "isobarometric" lines. It is certainly noteworthy that lines of equal barometric variation were drawn (1832) long before it was thought of constructing lines of equal air-pressure (isobars). These were first drawn by Renou (1864), and then particularly by Buchan (1869). Kämtz also remarked that his lines did not run wholly with the parallels of latitude, but that, *e.g.* the line of 8 par. lines = 18 mm., is met with on the east coast of the United States in 36° N. latitude, but in western Europe in 42°. At a much later period Fehlberg and Köppen again investigated the variations of air-pressure on a much broader basis, but also for the interval of a month (*Aus dem Archiv d. Deutschen Seewarte*, 1878, and *Meteorologische Zeitschrift*, 1883). These *monthly* barometer variations are naturally a much rougher measure of the irregular variations of pressure than the mean height of the individual pressure waves calculated by Dr. Lockyer. Köppen has already remarked that the lines of equal variations of air-pressure should be in relation with the direction of the tracks of the barometer minima.

[1] Solar Physics Committee. Southern Hemisphere Surface-air Circulation: Being a Study of the Mean Monthly Pressure Amplitudes, the Tracks of the Anticyclones and Cyclones, and the Meteorological Records of several Antarctic Expeditions. By Dr. W. J. S. Lockyer, under the direction of Sir Norman Lockyer, K.C.B., F.R.S. Pp. ix+111+xv plates. (London: H.M.S.O., Wyman and Sons, Ltd. Edinburgh: Oliver and Boyd. Dublin: E. Ponsonby, Ltd., 1910.) Price 6s.

Lockyer shows that, *e.g.* the Isanakatabar of 10 mm. in Australia coincides with the average track of the barometer maxima in that continent.

The next question was: with what velocity do these pressure waves progress from west to east.

By superposing the air-pressure curves of stations of different longitudes (first in Australia) and by shifting the time scale until the crests and troughs of the waves coincide, the difference of time of their occurrence at different places is indicated at once. In this way Lockyer obtains for the continent of Australia a daily velocity of progression of the barometric maxima from west to east of 11·5° of longitude, for South Africa, 12°, for South America, 11·1°, giving a mean of about 11·5°. The velocity over the oceans is naturally much more difficult to determine; Port Durban—Perth, gives for the South Indian Ocean about 9·5° a day; Adelaide—Rikitea, for the Pacific, 9·3°. Still more uncertain is the determination for the South Atlantic, which gives about 9·2°. Over the oceans therefore the barometric waves progress with less velocity. Lockyer gives 9·2° a day as the mean value (the Antarctic Ocean comes out as 9° to 10°). So we may adopt a general mean of 10·7°, whence it would follow that anticyclones travel round the earth in about 33·6 days. The author in no wise assumes therefrom that the anticyclones remain constant in form and intensity during their progression; on the contrary, they are subject to continual changes. He estimates their length of life on the oceans to be about six to seven days.

The wind and temperature observations, also, of all Antarctic expeditions, including the most recent one by Shackleton, are discussed in detail with reference to the problems of atmospheric circulation at present in question; series of barometric minima progressing from west to east are also shown. In longitude 30° to 90° W. the paths of the barometric minima appear from these observations (*Belgica* and *Scotia*) to lie more to the south than in the easterly longitudes. This seems to show that the centre of the Antarctic anticyclone is not at the pole itself, but in easterly longitudes, far therefrom, at the farthest, perhaps, in 130° E.

A coloured frontispiece, a chart of the southern hemisphere on the polar projection, gives a good schematic representation of the barometric minima and maxima that encircle the pole, and of the warm and cold air-currents proceeding from them. In the rear of the minima the permanent Antarctic anticyclone sends cold currents to lower latitudes, while, in front of them, warm air spreads to the Antarctic regions. These formations of the warm and cold currents gear into each other like toothed wheels, while they are constantly rotating round the pole.

With reference to the apparently permanent barometric maxima over the subtropical oceans, which lie nearer to the west than to the east coast of the continents in all oceans, Lockyer develops entirely new ideas which are very interesting and worthy of further examination.

The subtropical barometric maxima lie in the belt of anticyclones constantly travelling from west to east between lat. 20° to 40°. They are not fixed forms, and form no barriers to atmospheric circulation, but indicate only the spaces where the anticyclones which are actually travelling are mostly reinforced. Over warm land-surfaces anticyclones are weakened and partially effaced; over the cool sea-surfaces they are strengthened.[1] *They therefore arrive on the west coasts of the continents with greater intensity tha that with which they left the east coasts of the same*

[1] Perhaps I may here correct a slight error which has been taken from Buchan's "Meteorology." The specific heat of water is to that of firm land not as 4 to 1, but only 2 to 1. The question here is the "volume capacity," the specific heat for equal volumes. For dry ground this is 0·5 (for damp, about 0·6), compared to water. The ratio of specific heat for equal weights is only as 0·2 to 1·0.

This very interesting view could only originate i the study of the circulation of the air over th southern hemisphere, for in the northern, the condi tions are usually too complicated and disturbed b the land-surfaces.

The author deals only with the air-currents at th earth's surface. Nor does he go into the question o the nature and origin of anticyclones and cyclones He rightly confines himself to establishing facts which must certainly precede theories.

Dr. Lockyer's investigation, the contents of whic I have briefly sketched, is a very valuable contribu tion to our knowledge of atmospheric circulation Objections will probably be raised to many points but it is pure gain to the science if occasion is give for further discussion. For the simple reason tha the author does not follow the ordinary beaten track but presents entirely new views for examination, hi work will have a very stimulating and useful effect.

J. HANN.

THE INSTITUTE OF HUMAN PALÆONTOLOGY.

ATTENTION was recently directed in NATUR (January 26, p. 412) to the establishment by th Prince of Monaco of an institute of human palæonto logy in Paris. The council of administration has no been appointed; it consists of his Highness the Princ as president; MM. Dislère and E. Mayer, conseiller d'état; MM. Boule and Verneau, professors o palæontology and anthropology in the Muséum d'hi toire naturelle in Paris; M. Salomon Reinach, membe of the Institut and Conservateur of the Musée de antiquités nationales; and M. Louis Mayer, conseill intime of the Prince. On account of his great se vices to archæology and his administrative experienc Prof. M. Boule will be the director of the institut Two collaborators have been appointed: l'Abbé I Breuil, professor of prehistory and ethnography of th University of Fribourg, who will occupy the chair o prehistoric ethnography, and Dr. H. Obermaie privat-docent in prehistory at the University o Vienna, who will be professor of geology in its rel tion to prehistory.

We have frequently directed attention to th numerous and excellent researches of Prof. H. Breu upon the pictorial and glyptic art of Palæolithic ma Dr. H. Obermaier has been associated with Hoern and Penck in Germany, and Boule, Cartailhac, Breui and Capitan in France; he has made a special stu of glacial problems, and has investigated th Pyrenean region from this point of view. He h also published important papers on the form an stratigraphy of the older stone implements.

The professors will direct the explorations and e cavations undertaken by the institute, personally o with the aid of other specialists. The results will b published as monographs, in addition to short articles. During the dead-season they will give assis ance and instruction to students who desire to make serious study of fossil man. Lectures on the wor of the institute will be given to the general publ from time to time.

The institute will eventually possess an adequa library, specimens, and instruments; and not on will it bring to a focus all existing information on th subject of human palæontology, but it will be th main centre of all future researches. The stimulati and direction which the institute will afford will soo make itself felt, and in the near future we may loo forward to a considerable increase in our knowledg of the early history of mankind.

THE ETHNOLOGY OF YORUBA AND BENIN.[1]

ANYTHING which Mr. Dennett writes in connection with the Black man is bound to be of interest and importance to ethnologists; for even if they disagree with his ultimate theories and deductions they are ready to acknowledge the truth, and often the novelty, of the facts and observations he places on record. In many respects the book under review, which deals mainly with the Yoruba people of the western part of southern Nigeria, is superior to any he has as yet written, in that it contains more undoubted facts and accurate observations than deductions which set one's teeth on edge (as in "At the Back of the Black Man's Mind"), because they are based on insufficient evidence or lack of comparative study of other African races or languages. In fact, it may be said at once without too many qualifications that this work of Mr. Dennett on the Yoruba people is a remarkable book of permanent value to the ethnologist and to the student of Africa. It is, indeed, a special insight into the religious ideas of this highly developed negro people, from whom undoubtedly sprang the closely related art and civilisation of Benin, and most of the religious ideas to be found throughout southern Nigeria from Dahome to the Cameroons.

Yorubaland seems to have been invaded at a relatively early date by northern influence coming from Bornu, Hausaland, and the Fula and Songhai countries of the Upper Niger. We know from the interesting researches of Clapperton and Lander that in the early part of the nineteenth century the country of Borgu, which borders Yorubaland on the north, possessed amongst other evidences of northern influence a corrupted version of Christianity of some ancientness, said traditionally to have been brought there by Tuaregs or Berbers from the Sahara Desert. Similar traditions (accompanied by good collateral evidence) derived from Bornu or northern Hausaland most of the old dynasties of Borgu and other countries bordering the Lower Niger. It is, therefore, no difficulty to go a step farther and believe with Prof. von Luschan and other authorities that European influence penetrated far south into the Niger basin and the Cameroons before the times of Islam and the Roman Empire. Von Luschan can indicate in the Ethnographical Museum of Berlin very marked parallels between the art and the religious emblems of the Benue, Lower Niger, and Camerons regions, and those of Crete and ancient Greece. This analogy, again, quite independently, is pointed out by Mr. Talbot in the December number (1910) of the *Geographical Journal* ("The Land of the Ekoi"). Similarly, in reading Mr. Dennett's extraordinarily interesting description of Yoruba religious ceremonials and traditions, one is reminded of those of the Mediterranean peoples two thousand years ago and more. On p. 163 Mr. Dennett gives in Latin the exact text of the erotic songs declaimed by the women at a religious festival, which must have been very similar to the mysteries of Cybele and other similar phallic- and nature-worship manifestations of religion among the Greek and Latin peoples.

All that Mr. Dennett writes on the subject of marriage and totems (beginning on p. 176) is of great interest, and so far as the reviewer's knowledge goes, quite accurate. In connection with this, allusions are made from time to time in the book to the question of polygamy *versus* monogamy, and Dr. E. W. Blyden is quoted in defence of polygamy as being the system best suited to the negro race. With these opinions the reviewer differs. In his own books—especially that which dealt with the researches of George Grenfell on the Congo—he has given evidence to show that there is a greater proportional increase

Tree planted over Grave which thus becomes sacred. From "Nigerian Studies."

amongst negroes who practise monogamy—namely, cohabit with only one spouse, at any rate ostensibly—than amongst those who avowedly practise polygamy. The very conditions under which polygamy is practised in Africa limit to very few the number of children which each woman produces, nor does it follow necessarily that these few children are any healthier or better brought up than those which are the outcome of a monogamous union. In any case, this is almost indisputable: that the civilised negroes of the New World who profess to be monogamous—and are so, nearly as much as are the white people of the same region—are increasing at a faster rate than the polygamous peoples of Africa; are produc-

ing children quite as vigorous in physique and much better endowed mentally than the average native of Africa.

An interesting allusion is made in this book to the origin of fire, interesting because the native tradition quoted by Mr. Dennett is in accord with the observations and theories of several African explorers. On p. 216 he quotes the Yoruba legend that before man knew how to make fire, bush fires used nevertheless to occur almost yearly at the end of the dry season "when natural combustion took place." In Africa, at any rate, this was how fire became an agent of man. I have seen myself lightning set fire to a dead tree or to the dry grass near a tree, and thus start a bush fire in the dry season. Bush fires are very detrimental, in reality, to civilised agriculture in Africa. Nevertheless, in regions where the natives appreciate this fact and do not set fire to the grass or brushwood, bush fires occur from time to time in the dry season, and the natives assert that they are due to some natural cause, more especially to lightning, but also, it has been suggested, to some action of the sun, possibly of "a burning-glass" character acting through silica or some other mineral substance which concentrated the rays on to tinder. But lightning frequently starts a fire in Africa—as witness the cathedrals, barracks, hospitals, &c., which are burnt to the ground from this cause. The spread of the bush fire proved to be of enormous benefit to early man, since when he followed behind its ravages he was presented by nature with a variety of cooked or half-cooked beasts, birds, and reptiles. In this way he learnt the charms of cooked food and the usefulness of fire, and no doubt began to count on the annual opportunities offered to him in the dry season for the renewal of his household fire before he learnt to produce a flame artificially.

The chapter dealing with totems (p. 175 *et seq.*) is particularly interesting, and useful information is given on the laws and customs of land tenure.

H. H. JOHNSTON.

HIGH-FREQUENCY GENERATOR FOR WIRELESS TELEGRAPHY.

IT is announced in the daily Press that Dr. Goldschmidt has recently succeeded in sending wireless messages from Berlin to the South-Western frontier of Germany using his new high-frequency alternator to generate the electric oscillations. The production of undamped waves by means of high-frequency alternators has been the aim of numbers of inventors, as it is hoped that by producing a suitable generator it may be possible to avoid the defects of working that are associated with the usual arc and spark methods.

A number of alternators have been built, but owing to various reasons none of them have as yet come into extended use. Their design on the usual lines is very difficult, as even if the rotating parts are made to revolve at the highest speeds permissible from mechanical considerations, the number of poles required to produce the high frequencies necessary for wireless telegraphy is so great as to leave very little room for the windings, and the consequent cramping of the windings and great leakage between the closely spaced poles give rise to considerable drop of voltage when load is put on the machine.

Most of the machines that have been constructed hitherto have been of the inductor type, consisting of fixed windings placed under the influence of rapidly rotating armatures of iron containing a large number of projections or teeth, but the Goldschmidt machine is built on a quite different principle.

It is a phenomenon well known to those who have to work with single-phase alternators that when load is put on such machines the armature reaction causes double-frequency currents to flow in the field winding, and that these double-frequency currents cause triple-frequency currents to flow in the armature winding, and so on. This may be explained by the consideration that a stationary alternating flux can be regarded as being composed of two equal and constant fluxes rotating with equal speeds in opposite directions, the speed of the two fluxes being such that one complete revolution is made by them in the time of one period of the alternating flux.

Applying this to the case of an alternator with stationary alternating-current winding and rotating field system, it will be seen that if the rotating field produces alternating currents of a frequency f in the stator, the component rotating fields produced by the stator currents will rotate at the same speed as the field system, one in the same direction as the field winding, and therefore having no inductive effect on it, and the other in the opposite direction, and therefore inducing a current of a frequency $2f$ in it. A continuation of this process would cause currents of frequencies $2f$, $4f$, $6f$, &c., to appear in the field winding, and currents of frequencies $3f$, $5f$, $7f$, &c., to appear in the stator winding. The production of the higher frequency currents in ordinary alternators is limited by the fact that the amplitudes of the series of harmonics decrease rapidly owing to the great impedance opposed to their flow in the windings, but the triple-frequency harmonic superposed on the fundamental is often sufficiently marked to cause undesirable distortion of the wave-shape of the electromotive force of the machine.

Dr. Goldschmidt has constructed a machine in which the effect referred to is utilised to produce currents of very high frequencies, although the fundamental frequency of the machine is comparatively low. In order to prevent the damping out of the higher harmonics, he connects in parallel with the stator windings a series of capacity-inductance shunts tuned to resonance with the odd multiples of the fundamental frequency of the machine, and in parallel with the field winding a series of such shunts tuned to resonance with the even multiples of the fundamental frequency. Owing to the presence of these shunts the high-frequency currents are able to attain considerable magnitudes, and the electrical energy is reflected backwards and forwards between the stator and rotor of the machine a great number of times, the frequency of the oscillations being increased at each reflection until a frequency corresponding to the free period of the radiating circuit is reached.

In Dr. Goldschmidt's machine, oscillations of 120,000 cycles a second are produced, and the rated output is 12 kilowatts.

Practical experience of working will be necessary before it is possible to say to what extent machines of this type are likely to replace the present oscillation generators, but it seems not unlikely that difficulties will arise in keeping the frequency of the oscillations constant enough to enable clear signals to be received. It would appear that any small variation of the speed of the generator would cause each successive harmonic to depart to an increasing extent from its proper frequency, so that the final frequency reached might be so far removed from its proper value that signals would no longer be able to be received; added to this the amplitudes of the harmonics might be expected to be greatly diminished by the fact that a change of the speed of the machine would put all the capacity-inductance shunts out of tune with the harmonics for which they are adjusted, and a considerable weakening of the signals emitted by the aërial would result.

A. J. MAKOWER.

RECONSTRUCTION OF THE UNIVERSITY OF LONDON.[1]

THE period covered by Part ii. of Sir William Allchin's account of the reconstruction of the University of London[1] is comparatively short—three years, but it was an important period, that included attempts and failures that should afford valuable information to the Commission now sitting for the purpose of offering advice towards the further progress of reconstruction. The portion of Sir William Allchin's account now before us occupies, with the appendices, upwards of 500 pages; it presents the advantages, as well, perhaps, as the disadvantages, of a compendious Blue-book, containing numerous quotations from original documents, together with a detailed account from the point of view of a highly qualified witness of events in the order in which they developed, while, as indicated by the author himself, the account is substantially a compilation of actual documents; and although the period dealt with is very short, the compendious character of some of these documents is such that Part ii. by itself contains a reasonably intelligible, as well as a very authoritative, account of the process of reconstruction up to the date of the Selborne Commission of 1888. Although in some respects the difficulties of reconstruction have altered since 1891, the nature of the problem to be solved by the Commissioners remains the same, while the conditions to be fulfilled have become more apparent.

It is as clear to-day as it was twenty years ago that a real university is required in London; a university in which examination is not divorced from teaching, in which the teacher who has been the examiner of his pupils during their whole curriculum shall, with the cooperation and consent of an independent authority, "brand his own herrings." It is equally clear from the extension and development imposed by the force of circumstances upon the University of London—the examining body—when it was separated from University College—the teaching body—that upon the university of the metropolis devolves the duty of holding up to the British Empire the standard of excellence. There must be a university belonging to the great province of London, as there is a University of Manchester and a University of Liverpool, and there must be a university in London belonging, not only to London, but also to York or Toronto or Melbourne, and there must be in London, not two universities, but one university. On its metropolitan side, by force of geographical circumstance, it must include many colleges variously situated but under one common government. On its Imperial side it must say, "*Come and be tested,*" not only to the student at the end of his first few years of pupilage, but to the perpetual student, to the professor who has succeeded in learning something from Nature at first hand.

It is as true now as it was in 1888 to say that "it would be a mistake to constitute a local teaching university in London as a mere branch of a great examining body," and it would be an advantage now, as in 1888, if the title "London" were held by the teaching university, whilst the existing University of London should be styled "Imperial" (p. 32); and while it is probable that the new University of London would feed the old university, it is hardly less probable that the Imperial University of London would play its natural part in the intellectual commerce of the Empire.

[1] "An Account of the Reconstruction of the University of London." Compiled by Sir W. H. Allchin. Part ii. From the Appointment of the First Royal Commission to the Rejection of the Scheme of the Senate by Convocation, 1888 to 1891. Pp. vii+449+c. (London: H.M.S.O., Wyman and Sons, Ltd.: Edinburgh: Oliver and Boyd; Dublin: E. Ponsonby, Ltd., n.d.) Price 5s.

No one is better qualified than Sir William Allchin to present us with a clear account of the complication of causes to which the gradually progressive depletion of the London medical schools was attributable, and to the share in that depletion for which the University of London was responsible by reason of its high standards (p. 89). But recent history, and especially the comparative failure of the movement for the concentration of preliminary and intermediate medical studies, do not fall within the period dealt with.

Much water has, indeed, flowed under the bridges since 1891, and the final failure of the two teaching colleges on the one hand, and of the two royal colleges on the other, to produce, either separately or conjointly, any generally acceptable scheme of university organisation, are now matters of ancient history. Reconstruction has taken place under the advice of the Cowper Commission of 1892–4, and of the Statutory Commission of 1898, and the university reconstructed by the Commissioners appointed under the University of London Act, 1898, is now eleven years old; but it may be doubted whether the present structure can be regarded as possessing its definite and permanent form. The doubt expressed by the academic moiety of the Selborne Commissioners as to the possibility "of effectually combining the functions of an examining body, and of a teaching as well as an examining body, in the University of London," appears to have been verified by the progress of events, and advantage has been taken of the new fact of the foundation of the Imperial College of Science and Technology to bring the whole question of university reorganisation in London under the scrutiny of yet another Royal Commission.

The report in 1906 of the Departmental Committee on the Royal College of Science, suggesting that a Royal Commission should be appointed to consider what changes should be made in the character and constitution of the university, which would make it desirable to amalgamate an imperial college with the university, succeeded in the following year by the foundation of the "Imperial College of Science and Technology," and a year later by the request that a Royal Commission should be appointed for this purpose—have led to the appointment of the Commission of 1908, with terms of reference which have set before it a task of far greater scope and complexity than was allotted to either of the two previous University Commissions. Lord Selborne's Commission was instructed

> to inquire whether any, and what, kind of new university or powers are required for the advancement of higher education in London.

The terms of reference to Mr. Haldane's Commission, now sitting, are as follows:—

> To inquire into the working of the present organisation of the University of London, and into other facilities for advanced education (general, professional, and technical), existing in London for persons of either sex above secondary-school age; to consider what provisions should exist in the metropolis for university teaching and research; to make recommendations as to the relations which should in consequence subsist between the University of London, its incorporated colleges, the Imperial College of Science and Technology, the other schools of the University, and the various public institutions and bodies concerned; and, further, to recommend as to any changes of constitution and organisation which appear desirable. In considering these matters, regard should also be had to the facilities for education and research which the metropolis should afford for specialist and advanced students in connection with the provision existing in other parts of the United Kingdom and of his Majesty's Dominions beyond the Seas.

The dual character of the problem set before the Commissioners is clear enough in these instructions, but the duality is no longer restricted to the academic field of teaching and examination. The conflicting views of the teacher and of the examiner are but a small part of that problem, the "dualities" of internal and external interests, or of incorporated and non-incorporated colleges, or of academic and technological ideals, are dominated by the still more cogent duality of Metropolitan and Imperial.

The accidental development of an Imperial University under the Metropolitan name can be remedied and utilised in one way alone. The University of London is *de facto* the rough sketch of an Imperial University that should be distinguished by the name "Imperial." The Incorporated Colleges are *de facto* the nucleus of a Metropolitan University that should be distinguished by the name "London."

THE FUR-SEALS OF BERING SEA.

WE learn from *The Times* of March 17 that Russia has accepted an invitation from the United States Government to take part in a new Seal Fishing Conference at Washington a few months hence, probably in the spring of 1912, and Sir Edward Grey has announced in the House of Commons that an official invitation addressed to this country is now upon its way. It is generally understood that this invitation will be accepted, and that the Home Government, together with Canada, will take part in a friendly discussion upon this once difficult and contentious subject.

It is now eighteen years ago since the Paris Tribune of Arbitration gave its ruling, the gist of which was that, while the United States had no rights of property in the seals outside the ordinary three-mile limit, yet that in the special circumstances of the case it was desirable that that legal limit should be set aside and a wider boundary fixed; and as a matter of fact a close time was appointed, and a zone of sixty miles around the Pribyloff Islands was preserved against the operations of the "pelagic sealer." Three years later the question was again raised by a celebrated letter addressed to our Ambassador by Mr. John Sherman; but after inspection of the seal-rookeries by British experts, and a re-discussion of the whole circumstances of the case at Washington, no sufficient reason was found for disturbing the decision of the Tribunal, and the case has since remained *in statu quo*.

During the thirteen or fourteen years that have elapsed since the Washington conference no inspection of the rookeries has taken place by British agents, and but little news concerning their condition has reached this country; but there can be no doubt at all that the herds have greatly deteriorated during these recent years. The American agents declare that the seals are now only one-fourth as many as at the time of the arbitration, when already the diminution had gone far. At the same time, the Canadian sealing fleet has dwindled almost to nothing, and accordingly the responsibility for the recent depletion of the herds must lie on other shoulders than our countrymen's.

It appears that it is now the Japanese who are mainly responsible. As Japan was no party to the Paris Arbitration, the sixty-mile limit has never applied to them, and the Japanese sealers accordingly ply this trade around both the Russian and American islands right up to the three-mile limit, and (if report says truly), even sometimes to the very shore. During the years of the Russo-Japanese war it is said that the Commander Islands were freely pillaged, and it is certain that nowadays the Japanese fleet—non-existent a dozen years ago—is both large and active. In 1908, it is said by the United States agents that the Japanese fleet consisted of no fewer than thirty schooners, some with as many as sixteen boats, and rumour has it that our own countrymen in British Columbia have attempted to put their vessels under the Japanese flag, so as to evade exclusion from the sixty-mile zone. It is believed that Japan has agreed to take part in the impending conference if Great Britain likewise agrees to participate, and there is thus every reason to hope that an arrangement may be come to by which the destruction shall be arrested, and the herds gradually restored.

PROF. JAKOB MAARTEN VAN BEMMELEN.

IN the death of Prof. van Bemmelen, which took place on March 13, there passes away the oldest member of that singularly distinguished band of chemists and physicists which has had its home at the University of Leyden.

Born on November 3rd, 1830, at Almelo, where his father was head of the Grammar School, Prof. van Bemmelen was in his eighty-first year at the time of his death. His father died in 1830, and the widow moved to Leyden, where her son attended the High School, until he entered the University in 1847. He studied chemistry under the then professor of chemistry and pharmacology, van der Boon Mesch. Van Bemmelen has himself left on record a description of the very primitive laboratory—a single room with wide old-fashioned hearth in the great St. Catherine Inn in Breedestraat, serving as lecture-room and laboratory. There, as he notes, chemical instruction could go no further than the simplest quantitative experiments!

In 1852 van Bemmelen became assistant to Prof. van Kerchoff at Groningen, and it is owing to the fact that the students were mostly interested in pharmacology that his earliest papers were purely pharmacological in character.

Van Bemmelen's life work, his investigation of the colloidal state, came to him when he left Kerchoff to become teacher in the School of Agriculture at Groningen. There he began his analysis of soils, and there also, in 1864, he began to experiment on the "absorption processes in mould," the results of which were not published until 1877, thirteen years later. This delay was due to pressure of other work, largely alien to the young chemist's tastes. In 1858 he had married the daughter of the Rev. Jan Boeke, Baptist minister at Amsterdam, a lady whom the writer remembers as a gracious and kindly hostess at Leyden ten years ago, and the necessity for providing for his home led him to accept with much misgiving the position of director of the High School at Groningen when it was offered in 1864. There he stayed for five years, with little time or opportunity for laboratory work, and, as he himself has recorded in the Gedenkboek of the school, much distressed at the slow progress he could make in his studies of absorption. In 1869 he was moved to the High School at Arnheim, where he remained until the final move to Leyden in 1873.

Though the chief work scarcely progressed at all during these years of school administration, they were not wholly barren of scientific work. More than twenty papers were published, all on problems of agricultural chemistry. To this period also belongs what van Bemmelen himself very characteristically called his greatest contribution to chemistry—the discovery of Bakhuis Roozeboom, who came to assist him in soil analysis.

In 1873, the chair of chemistry at Leyden becoming vacant owing to the retirement of van der Boon Mesch, Dr. van Bemmelen was elected into it, and Bakhuis Roozeboom became his assistant. The first ten years of the professorship were almost exclusively devoted to the chemistry of soils, and the results place van Bemmelen in the front rank of agricultural chemists. Thenceforward, from 1880 onwards, the rest of his long and active life was devoted to elucidation of absorption as a phenomenon of the colloidal state.

In this region van Bemmelen ranks as a pioneer, and his fame rests now, and must always rest, on his classical researches on the relations between the components in the hydrogels of various colloidal oxides.

The work is in the main experimental and descriptive. It embodies an enormous amount of exact observation which has not yet been fully assimilated into the general body of knowledge. In one marked respect van Bemmelen stands apart from the Dutch school of chemists. With the exception of an address on the application of thermodynamics to chemistry which he delivered when rector of the university of Leyden in 1889, van Bemmelen's work is non-mathematical. His colloidal work is the application of the old-fashioned descriptive and experimental methods to a new region. His first assistant, Roozeboom, and his second assistant, Schreinemakers, on the other hand, were purely of the thermodynamic school.

Van Bemmelen possessed great personal charm. No picture which the present writer has seen does justice to features which were singularly delicate and refined. As the descendant of an old Dutch family, he was somewhat of an aristocrat in altogether the best sense of the word. Although his devotion to science was intuitive and instinctive, it left space for many interests amid the "humanities." As his life-long friend and colleague in the professoriate, Prof. Tiele said of him:—"Although an assiduous investigator in special fields of learning, van Bemmelen always bore in mind those greater questions the answering of which is the aim of us all."

W. B. H.

DR. JOHN ATTFIELD, F.R.S.

ON Saturday, March 18, Dr. John Attfield passed to his rest, and scientific pharmacy lost one who had devoted much of his life and work to its advancement.

Born in 1835, Attfield, after the completion of his school education, became a student in the School of Pharmacy of the Pharmaceutical Society, and subsequently demonstrator of chemistry at St. Bartholomew's Hospital, a position which he occupied for eight years. In 1862 he graduated at the University of Tübingen. In the same year he was appointed director of the laboratory of the Pharmaceutical Society, and soon afterwards professor of practical chemistry, a chair which he filled for thirty-four years. During this long period Attfield devoted himself, with marked success, to the advancement of pharmacy and particularly of chemistry as applied to pharmacy. His industry and ability in this respect is attested by the long series, some seventy in number, of original articles that appeared under his name in the *Pharmaceutical Journal* and other journals, an industry and ability that was soon to be rewarded by the blue ribbon of science, the Fellowship of the Royal Society. Of his publications the most important, and that which undoubtedly had the most far-reaching influence, was his "Handbook of Practical Chemistry," a work which was quickly accepted, both in this country and abroad, as an ideal text-book for students of pharmacy.

But it was not by his scientific labours alone that Attfield accomplished so much for pharmacy. Himself an admirable organiser and possessing extraordinarily methodical habits, he took an active part in founding the British Pharmaceutical Conference, an association that has proved itself of inestimable value to pharmacy, and later the Institute of Chemistry. To the subject of pharmaceutical education he devoted much time and attention, and no more strenuous advocate could be found of the advantages that would accrue to pharmacy through the raising of the standard of education amongst its members. Further scope for Attfield's scientific ability and inclination presented itself in the editorship of the "British Pharmacopœia" and of two of its addenda. The pages of these works bear abundant testimony to the care and skill that was bestowed upon them.

To his students Attfield was a genial, kindly teacher, ready at all times to sympathise with them, to assist them in their difficulties, to encourage them by becoming a student himself, and to stimulate them by holding up to them an ideal towards which they should strive. Much as he accomplished directly, it was little compared with what he accomplished indirectly by organising others and directing their efforts. During the thirty-four years of his teaching career many hundreds of students passed through his hands; there is not one that does not owe a debt of gratitude to John Attfield.

HENRY G. GREENISH.

NOTES.

THE annual meeting of the British Science Guild will be held at the Mansion House on Friday, April 7, at 4 p.m. The Lord Mayor will preside, and the president (Mr. Haldane) and others will address the meeting.

MR. F. J. BRIDGMAN, demonstrator in zoology and curator of the zoological museum of the Imperial College of Science and Technology, South Kensington, has been appointed naturalist on the staff of the Plymouth Laboratory of the Marine Biological Association.

ALTHOUGH attacked by a destructive epidemic some two or three years ago, wood-pigeons have of late increased to such an extent that measures are being taken to diminish their numbers. Some letters have appeared in the public Press directing attention to pigeon diphtheria and its risk to man. Pigeon diphtheria, however, has nothing to do with human diphtheria; the micro-organism is quite different, and is probably very minute and a "filter passer."

AN influential deputation from the Royal Institute of Public Health waited on the Presidents of the Local Government Board and Board of Agriculture and Fisheries on March 16 to urge the necessity for appointing a Royal Commission for the purpose of inquiring into (1) the increase of vermin and the steps to be taken for their destruction; (2) the question of what creatures are or are not harmful to man and his industries; and (3) the safety and efficiency of the various viruses on the market and other means advocated for such destruction. Mr. Burns acknowledged the influential nature of the deputation and the importance of their representations, and promised consideration of the matters brought before him.

The Popular Science Monthly for March contains an interesting article, by Dr. Fielding Garrison, on Ehrlich's work on specific therapeutics and on "salvarsan" in

particular. This drug, introduced under the name of "606," is an organic arsenic compound (dioxy-diamino-arsenobenzol), and has an almost specific curative effect on diseases caused by spirillar micro-organisms, such as relapsing fever and syphilis. For the latter a single dose often suffices to cure, whereas the ordinary mercurial treatment must be continued for months.

In a presidential address delivered before the Society of American Bacteriologists, Prof. Veranus Moore pleads for the inclusion of bacteriology in the curriculum of the schools for the masses. He argues that information concerning the cause of fermentations, the storing of nitrogen in the soil, the causes of the changes in food-stuffs, and the etiology of the common infectious diseases, is as important, or the acquisition of such knowledge of as much disciplinary value, as the study of the life-history of the denizens of the deep as now required in many, if not in most, biological courses.

We record with regret the death of Lord Airedale, on March 16, at seventy-five years of age. Lord Airedale, who was perhaps better known under his earlier name as Sir James Kitson, devoted himself to the construction of locomotives suited to the characteristics of the countries for which they were required. He was president of the Iron and Steel Institute from 1888 to 1890. In 1904 he was awarded the Bessemer gold medal "for distinguished services to the iron and steel industries of Great Britain." The University of Leeds conferred upon him the degree of Doctor of Science.

The necessity of a systematic investigation of the prehistoric antiquities in the Balkan Peninsula has been impressed upon English scholars by the important results which have already followed the partial examination of a few of the more promising sites. It is now recognised that this region holds the key to many problems beginning from the early age of Greece and extending to the period of the Byzantine and Bulgarian kingdoms. A new phase of Neolithic culture independent of that of Crete has been identified in Thessaly, and on the Adriatic coast the relationship between the Balkan peoples and those of southern Italy, which is indicated by recent discoveries, needs clearer definition. With the object of exploring these regions, an influential committee of Oxford and Cambridge scholars has been formed, with Dr. A. J. Evans as chairman, Prof. J. L. Myres as secretary, and Mr. Vincent Yorke, The Farringdon Works, Shoe Lane, London, E.C., as treasurer, who invite contributions to a project which is sure to command the approval of all who are interested in the prehistoric culture of the Ægean area.

The annual awards of the Royal Geographical Society have been made as follows. The two Royal medals have been awarded to Colonel P. K. Kozloff, who receives the Founder's for his explorations in Central Asia since 1883, and to Dr. J. Charcot, who receives the Patron's for his expeditions to the Antarctic continent, first in 1903–5, and second in 1909–10. The Victoria research medal has been awarded to Captain H. G. Lyons, F.R.S., who was for many years the Director-General of the Egyptian Survey Department. During his tenure of office he carried through the cadastral survey of Egypt. Captain Lyons is at present lecturer in geography at the University of Glasgow. The Murchison bequest has been awarded to Dr. Wilfred Grenfell for his many years' work in Labrador. The Gill memorial goes to Captain G. E. Leachman, of the Royal Sussex Regiment, for the journey he made last year in north-eastern Arabia. The Back bequest goes to Dr. Arthur Neve, who has resided in Kashmir for many years, and devoted himself to the investigation of the Himalayas. The Cuthbert Peek fund has been awarded to Mr. R. L. Reid, who, during his six years' residence in the northern portion of the Congo State, carefully mapped the whole of the Mobangi River.

We regret to record the death of Dr. Otto Puchstein, secretary of the Imperial Institute of Archæology in Berlin, and one of the leading authorities on classical archæology, especially in its relations to Western Asiatic culture. Dr. Puchstein, who was born in 1856, studied archæology in Strassburg, and it was while he was still at the University that he undertook a careful examination of the Greek inscriptions which had been brought back by Lepsius from Egypt, his resulting dissertation obtaining him his doctor's degree in 1880. His first journey in Kurdistan, which largely determined the trend of his later studies, took place two years later, when he was commissioned by the Berlin Academy to report on the tombs recently discovered by Herr Sester, the engineer. The direct result of this report was the organisation by the Academy of a more important expedition to Asia Minor, on which Puchstein accompanied Prof. Carl Humann and Prof. von Luschan. The work recording the results of the expedition, entitled "Reise in Kleinasien," and illustrated as it is from most successful photographs, is still our principal authority for the remains of Hittite art. In his brochure "Pseudohettitische Kunst," and his suggestive studies of the origin of the Ionic column, he made full use of his wide acquaintance with eastern archæology. Of his other works, the most important were his monograph, in two volumes, on the sculptures of Pergamon, and the work, produced in collaboration with Dr. Robert Koldewey, on the remains of south Italian and Sicilian temples. Since 1885, in addition to other duties, he had held the post of assistant director of the Royal Museum in Berlin.

In *The Fortnightly Review* for March, Mr. W. S. Sparrow attempts to solve the problem how the primitive round house became square and oblong. He traces this transition from the period of the long barrows through the bee-hive houses on the island of Skellig Michael in Kerry. The necessity, as agriculture developed, of forming a winter shelter for cattle, led to the adoption of the oblong shed, the ends of which were supported by the forked tree known as gavel or crutch. This form of shed architecture came gradually to be extended to the round family hut as the needs of social life gave rise to the demand for larger roofed structures, which could not be provided in the circular building, and as the growth of the power of the chief made it necessary for him to sit on a dais at some distance from his retainers. The adoption of the crutch as a roof support naturally led to the practice of doing away with the curved spaces at the sides of the house by flattening the outer wall, which, as in the lake village of Glastonbury, then came to be made of long hurdles.

Some of the papers in ser. 3, vol. xiii., of the *Anales del Museo Nacional de Buenos Aires* (of which we have just received a complete copy), having been already noticed in Nature as they were separately issued, it will suffice to refer to an article on totemism, by Prof. L. M. Torres, which forms the concluding portion of the volume. This contains a long review and collation of the various theories and opinions as to the origin, signification, and effects of the totem cult, together with the author's own views and conclusions.

In the course of a note on the local seals in *The Irish Naturalist* for March, Dr. R. F. Scharff states that a seal which lived for some time in the Dublin Zoological

Gardens, and was taken in Galway Bay in 1895, turns out to be *Phoca foetida*, a species of which there appear to be extremely few previous British records. Dr. Scharff refers to certain dental characters by which the ringed seal may be distinguished from *P. vitulina*, but omits to mention a much more important difference between the two. In the common seal the two branches of the lower jaw form a very short union in front, but in adult specimens of the ringed seal the symphysis is of great length, almost recalling, in miniature, that of a sperm-whale. So great is the difference in this respect between the two species, that it affords considerable justification for Gray's generic separation of the ringed seal.

Two papers on armoured dinosaurs have recently appeared in *The American Journal of Science*. In the first (December, 1910) Mr. R. S. Lull describes the skeleton, or rather the compound skeleton, for it is made up of two individuals, of *Stegosaurus ungulatus*, recently mounted in the Peabody Museum of Yale University. This is claimed to be the first reconstructed specimen with the bones in their proper position, and with the dorsal plates in two parallel rows. A restoration of the external form of this strange reptile is also attempted. In the second paper (February, 1911) Mr. G. R. Wieland suggests that even Mr. Lull's restoration is incomplete, for he claims to have evidence of the existence of a series of low pleural keels in addition to the large dorsal plates. In this communication Mr. Wieland furnishes additional particulars with regard to the dermal plates and other remains described under the name of *Hierosaurus sternbergeri*. These, it is stated, indicate a reptile of about 5 metres in length, and therefore about half the size of Stegosaurus. Possibly they may prove generically inseparable from the previously named Stegopelta.

We have received a copy, bearing the date of May, 1910, of an important memoir, by Dr. O. Abel, on the early Tertiary rhinoceroses of Europe, published as part iii. of vol. xx. of *Abhandlungen der k.k. Geologischen Reichsanstalt*, Vienna. The author adopts the view that the rhinoceros group should be divided into three families, namely, Hyracodontidæ (including Hyrachyus as well as Hyracodon), Amynodontidæ, and Rhinocerotidæ, each of which has undergone divergent development. No fewer than four new generic terms are proposed for the European early Tertiary representatives of the latter, the first two of these being based, respectively, on Cuvier's *Rhinoceros minutus* and Filhol's *Aceratherium minus*, while the other two are established as new species, one from the lignite of Monte Bolca and the other from the Oligocene of Krain. Special classificatory importance is attached to the fourth upper premolar, of which the oldest type is found in Hyrachyus, where the two cross-crests converge on the inner side to form a **U**-like loop. From this we find a gradual transition in the early Tertiary European forms to the modern Rhinoceros type, in which the last molar has become molariform with sundered and parallel cross-crests. Progressive increase in the complexity of the upper molars is likewise noticeable. The proposed emendation of the name *Prohyracodon orientalis* to *P. orientale* is uncalled for.

The fourth volume (185 pp.) of Papers from the Tortugas Laboratory of the Carnegie Institution of Washington contains three contributions:—(1) An account, with text figures, by Prof. H. S. Pratt, of the anatomy of *Monocotyle floridana*, a new monogenetic trematode from the gills of the whip-ray (*Myliobatis freminvillei*). (2) A systematic survey of the trematodes of the Dry Tortugas, by Prof. E. Linton, in which are described, and figured on twenty-eight plates, thirty new genera and eleven new species of previously known genera. The author, while disposed to regard the generic limits proposed by modern helminthologists as being too narrow, is not prepared to suggest, at present, any change in the conception of what should constitute a generic character in the Trematoda; he has chosen to make this large number of new genera, all of which, except three, are represented by a single species, rather than to extend the limits of those already known. (3) Dr. Wayland Vaughan's contribution to the geological history of the Floridian Plateau, which he traces from Lower Oligocene time to the present, includes detailed studies on the geology, topography, bottom deposits, and on the transporting agents and their effects. The account is illustrated with maps, figures, and photographs.

The March issue of *The Naturalist* contains a revised check list of British earthworms, by the Rev. Hilderic Friend. It is nearly twenty years since the previous list was issued, and in the meantime a dozen new species have been discovered by the compiler, and several important varieties. The additions to the former list include *Aporrectodea similis*, Fr., found at Kew last year, and described in *The Gardeners' Chronicle* of August 6, 1910; also *Dendrobaena submontana*, Vej., *Octolasion intermedium*, Fr., from Oxford, *Eophila icterica*, Sav., from Cambridge and Chelsea, *Allolobophora alpina*, Rosa, and *Allurus hercynius*, Mich., from Scotland, and the two interesting worms *Allolobophora hermanni*, Mich., and *Helodrilus oculatus*, Hoffm., which Michaelsen in his "Tierreich" regards as one and the same species. The list contains thirty-five species, besides several varieties, chiefly under the heading of *Eisenia veneta*, Rosa. One entirely new name also appears, but it is at present doubtful whether *Helodrilus elongatus*, Fr., found last year in Cornwall, may not have to be relegated to another group. It may possibly be a Sparganophilus. The author has overlooked the fact that *Bimastus beddardi*, Mich., was found by himself in Ireland, but described as a variety of *B. constricta*, Rosa. As he is preparing a monograph of British earth- and water-worms for the Ray Society, he appeals for help to make his researches complete.

Under the title "The Native Camphor Trees (Cinnamons) of Australia," a paper was read by Mr. R. T. Baker, curator of the Technological Museum, Sydney, before the biological section of the Australasian Association for the Advancement of Science, held in Sydney in January last. In this paper the author endeavours to show that the Australian species hitherto recorded are all endemic, and makes use of anatomical and chemical characters as auxiliary to the morphological characters usually relied upon in discriminating between the species. The appearance of the paper itself will be looked for with considerable interest.

We have received copies of *The American Review of Tropical Agriculture*, a monthly journal, still in its first year of issue, devoted to the agriculture of those tropical countries in which America is particularly interested. It is published in Mexico under the editorship of Dr. Pehr Olsson-Seffer at the price of 15 c., and is intended for scientific and technical communications rather than mere newspaper items. Nos. 5, 6, and 7, which have already come to hand, contain articles on rubber and on the desert rubber-bearing plant, guayule (Parthenium).

Three bulletins received from the Bureau of Entomology of the U.S. Department of Agriculture deal with insect pests of fruit trees. Mr. Hammar describes the life-

history of the codling moth, *Carpocapsa pomonella*, in north-western Pennsylvania. In Bulletin No. 80, part vii., are given details that must be observed in spraying for this moth and for the plum curculio. The details for spraying with paraffin oil and other washes against the scale insects are set out in Bulletin 80, part viii. In another Bulletin (No. 82) are notes on the cucumber beetles, Diabrotica sp. Circular 122 describes the work done in combating the cotton-boll weevil, perhaps the most expensive insect in the States.

WE learn from the Journal of the National Poultry Organisation Society, No. 1, vol. v., that considerable progress has been made during the last twelve months in organising the industry. Indeed, Mr. Brown estimates that we now produce 5,000,000*l*. per annum more eggs and poultry than fifteen years ago. In Ireland particularly great advances have been made, and at the present time the production is considered to be *pro rata* greater than in any other country. Wales and Scotland are, however, only now awakening to the possibilities in this direction. The supply of cheap foreign eggs apparently cannot be relied upon to continue indefinitely, and increased home production is considered necessary if an egg famine is to be avoided.

THE possibility of growing sugar beets in South Africa is discussed by Dr. Juritz in *The Agricultural Journal of the Cape of Good Hope* (No. 5, vol. xxxvii.). As the soils of Cape Colony are better supplied with potash than with other plant foods, in particular, lime, it seemed *a priori* probable that crops rich in sugar could be obtained, and this expectation has been realised. Beets have been grown containing 15 to 16 per cent. of sugar, and comparing very favourably with crops obtained in Germany and the United States. There still remain, however, a number of details to settle before definite steps can be taken to grow the crop on a large scale. All experience indicates that sugar beet is somewhat expensive to produce by reason of the labour and manure required.

THE reduction of timber supply through the destructive action of insect pests forms the subject of recent circulars (Nos. 127, 128, and 129) issued by the United States Department of Agriculture Bureau of Entomology. The annual loss is estimated at about 62,500,000 dollars, but part of this, at any rate, could be saved by utilising damaged timber as early as possible. Indeed, it is considered that the removal of insect-infested timber would do more than anything else to reduce the number of insects and strengthen the control. In Circular No. 125 some of the insects are described, and methods of control are suggested. Bulletin 94 deals with the injury done to chestnut telephone and telegraph poles by wood-boring insects, especially *Parandra brunnea*, Fab., the life-history of which is described in detail. The oak pruner, *Elaphidion villosum*, Fab., is described in Circular 130. It cuts off twigs and small branches, and sometimes even fells young trees.

ON looking through Indian forestry publications and records, it is evident that experience and opinions vary considerably with regard to the best methods for regeneration of forest trees from seed. Considering the great variety of trees and the diversity in soil and climate this is natural, and therefore actual records of observation and experimental seedling plantations are much needed. In the Indian Forest Records (vol. ii., part iii.), Mr. D. O. Witt discusses the sylviculture of *Hardwickia binata*, "anjan," with special reference to the Nimar district of the Central Provinces, and Mr. M. Rama Rao presents a note on the germination and growth of sandal seedlings. Mr. Witt adduces evidence for the contention that successful growth of anjan seedlings depends primarily on a sufficient water supply combined with shade during the hot weather; in addition, preservation is required from grazing, and fire protection is desirable. The paper also contains information with regard to localities, composition, and regeneration of anjan forests.

THE new interpretation, preferred by Prof. E. C. Jeffery, of the structure of certain coals, notably of bogheads, is elaborated, with evidence derived from microscopic sections, in the Proceedings of the American Academy of Arts and Sciences (vol. xlvi., No. 12). On the authority of the two famous French palæontologists Prof. C. E. Bertrand and Mr. B. Renault, the explanation has been accepted that boghead coals are largely composed of colonies of gelatinous algæ, to which the name *Pila bibractensis* has been assigned. This explanation is disputed by Prof. Jeffery, who asserts that the thinner microscopic sections prepared by improved methods reveal the presence, not of algæ, but of spores of vascular cryptogams. It is significant that the spore structure is more pronounced in American and Scotch boghead coals than in the bituminous schists originally investigated by Bertrand and Renault. Prof. Jeffery's interpretation has a wider bearing, inasmuch as it undermines the algal hypothesis of the origin of petroleum.

IN *The Times* of February 28 is a description of the falls of the Mayo Kebi river, furnished by Mr. P. Talbot, whose party are apparently the first Europeans to visit them. Rising in French Equatorial Africa a little south of the tenth parallel, this river plunges down cliffs some 60 feet high, and flows on to join the Benue river on its way to the Atlantic. These cliffs and the gorge below are of granite, and form part of the ridge which here separates the Niger-Benue basin from that of the Shari flowing to Lake Chad.

As a contribution to the hydrography of the basin of the Seine, M. E. Clouzot gives in *La Géographie*, xxiii., 2, an account of the inundations of Paris in the past due to high levels in the Seine. From the sixth century the banks have been submerged from time to time, but it was only in the middle of the seventeenth century that the question of adopting means for mitigating the results of these occurrences was actively discussed, largely owing to the damage wrought by the great floods of 1649, 1651, and 1658

DR GROLL in the *Zeitschrift der Gessellschaft für Erdkunde* for February discusses the imperfect representation of the ocean floor in the light of the comparatively few soundings which are available when the area for investigation is considered. Difficulties in accurately locating points of observation enter into the question also, but even so, if areas are selected where the most detailed surveys have been carried out, the material is sufficient to show that much of the uniformity shown in physical maps arises from over-generalisation or imperfect information.

MR. W. GOODFELLOW, who had to return from the British Ornithological Expedition in New Guinea on account of ill-health, communicated a short summary of his experiences to *The Times* of March 3. He describes the extreme difficulties met with in cutting a way through the dense forest in the low country near the Mimika river. Starting from this river, and pushing inland, it was found eventually that it would have been better to have followed a river lying farther to the eastward, since on reaching the head of the Mimika the expedition had to cut its way eastwards through the forest, a task which

was still in hand when Mr. Goodfellow left. The snow-capped mountain range rose steeply from the country at its foot, and is inaccessible at most points. The heavy rainfall in this range causes the rivers to rise rapidly in flood, by which parties of the expedition were held up for days unable to move. In spite of such obstacles, and the flooded condition of much of the forest region, much careful mapping, both of the Mimika and other rivers, and of a part of the mountain range, has been effected. Collections of birds, mammals, and ethnological objects have arrived in England for study, but a large part of the material obtained has yet to be received, including the reptilian and entomological specimens.

THE Board of Agriculture and Fisheries has just published a memoir of the Geological Survey on the water supply of Sussex (supplement). The memoir contains much new information which has accumulated since 1899, when the original memoir was published. The subject is dealt with under the headings of rainfall, springs, and risks of contamination. Details are given of a large number of wells and borings, together with analyses of waters. A general index, covering the original memoir as well as this supplement, is included. Copies may be obtained, price 2*s*. 6*d*., from any agents for the sale of Ordnance Survey maps, through any bookseller, or from Mr. T. Fisher Unwin, 1 Adelphi Terrace, London, W.C., who is the wholesale agent for the sale of Geological Survey memoirs in the United Kingdom (except in the County of London).

THE "Instructions to the Marine Meteorological Observers of the U.S. Weather Bureau" (third edition), a copy of which has reached us, are very complete, and contain much useful information for general readers interested in meteorology. Some photographs of types of fog in the vicinity of San Francisco are very noteworthy. Instead of several sets of observations required daily by the former log-book, only one observation daily (except in the case of storms) is now asked for, to be taken at Greenwich mean noon. This large reduction in the number of observations required has resulted, as was hoped, in a great increase in the number of observers, which now amounts to about 3000. These daily simultaneous observations taken over the entire sea are first plotted on charts for the study of weather changes as they actually occur; afterwards they are tabulated, according to months, in 5° squares of latitude and longitude, and published in the monthly meteorological charts issued by the Bureau and in the Pilot Charts issued by the Navy Department.

MR. G. W. PIERCE, author of "Principles of Wireless Telegraphy," goes into the question of the best arrangement of the circuits at a wireless receiving station in a paper which appeared in the January number of the Proceedings of the American Academy of Arts and Sciences. The distributed capacity of the antennæ is treated as localised to simplify the calculations, and the results obtained will be sharper and more definite than can be expected in actual practice. The author finds that best resonance may be obtained with two values of the wave-length of the receiving circuits either above or below that of the incident waves. He points out the advantage of a low-resistance detector circuit on account of the superior sharpness of the resonance effect obtained, and considers that what is now required is a low-resistance detector with a high efficiency which shall convert rapid into slow alternate or into direct currents.

The Electrician for March 3 contains an abstract of a paper, presented to the Franklin Institute at Philadelphia by Mr. Carl Hering, in which it is claimed that a conductor carrying an electric current is subjected to a stretching force. In support of this statement, the author describes some of the well-known experiments, or modifications of them, in which a circuit carrying an electric current increases its area if any portion of the circuit is movable. The trough experiment of Ampère, in which a floating conducting bridge connecting two parallel troughs of mercury moves away from the ends of the troughs at which the current enters and leaves, respectively, may be cited as an example. The "pinch" effect, that is, the tendency of a liquid conductor carrying a current to contract in section, which was discovered by Mr. Hering, is given as a further proof of the stretching to which the conductor is subjected. In our opinion, the view taken by *The Electrician* in its leading article on the subject is the more natural one, namely, that the whole of the movements are explained by the repulsion by each other of the magnetic lines of force of the various parts of the circuits.

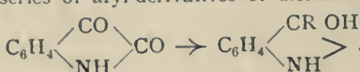
IN connection with the resistance-thermometer method of demonstrating the existence of the Peltier and Kelvin thermoelectric effects described by Mr. Starling in our issue of February 16, Prof. W. König, of Giessen, has directed our attention to two recent papers of his in the *Physikalische Zeitschrift* and in the *Archives* of the Swiss Société de Physique, in which he describes a very simple optical means of demonstrating the existence of the Kelvin effect. The material is a **U**-shaped wire, the bend of which dips into a mercury bath. The electric current passes down one and up the other side of the **U**, and its magnitude is so adjusted that the wire becomes red hot for a short portion of its length. The two red patches are found to be displaced upwards or downwards with respect to each other, according to the sign of the Kelvin effect in the material of the wire. Owing to the complicated nature of the heat losses from such a wire, Prof. König has not been able to make the method quantitative.

WE have received from Messrs. E. Leitz, of Wetzlar, and Oxford Street, London, copies of their catalogues of projection and photomicrographic apparatus. It is an indication of the importance at the present time of such appliances in scientific and educational work that these complete catalogues are compiled and issued separately. Until comparatively recent times such descriptions would have been included in a general catalogue; in fact, even now it seems to be reserved to foreign manufacturers to treat such matters with that thoroughness of which this is a typical example. The apparatus described is, in many cases, designed and constructed on established lines, but in others, particularly in the application of photography to micro-metallurgical work, the arrangements are both novel and ingenious. The ordinary worker is particularly indebted to Messrs. Leitz for introducing a small type of arc lamp, which is of great efficiency considering its small current consumption, may be used on any house supply without special wiring or fitting, and yet gives sufficient light for even the highest power photomicrographic work. Both optically and mechanically the products of the firm now take a high place, and an inspection of the apparatus referred to is sufficient to demonstrate that it is well thought out by those who have practical experience of the requirements of the worker in each particular branch.

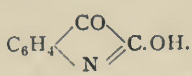
SOLID ammonium nitrite was isolated a year ago by Rây, who showed that small quantities of the salt sublime with decomposition when a dilute solution (0·7 to 2·0 per cent.), prepared by the interaction of silver nitrite

with ammonium chloride or of barium nitrite with ammonium sulphate, is gently heated in a vacuum. It has now been shown by Messrs. Neogi and Adhicâry, of the Rajshahi College, Bengal (Journ. Chem. Soc., February), that the salt may be obtained in fairly large quantities by evaporating and subliming in a vacuum a very concentrated solution of ammonium chloride mixed with sodium or potassium nitrite. The evaporation is carried out in an exhausted distilling flask connected with a condenser and heated by means of a paraffin bath at 50°–60° C., the Geryk pump being worked constantly when the critical moment is reached at which solidification begins. The temperature is then raised gradually to 80°, when the solid nitrite begins to sublime, and forms a thick crust in the upper part of the flask. The salt, which was analysed by a variety of methods, is extremely hygroscopic, but may be kept undecomposed in an ordinary desiccator or in sealed tubes; in a vacuum desiccator the salt is decomposed by the action of the acid on its vapour. Ammonium nitrite is volatile with steam, and does not explode when reheated; vapour-density determinations at 100° showed that the salt had decomposed completely into nitrogen and steam.

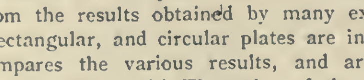
AN interesting contribution to the chemistry of the indigo-group is described in the *Sitzungsberichte* of the Vienna Academy by Prof. M. Kohn, who has acted upon isatin with the Grignard reagent in various forms and obtained a series of aryl-derivatives of dioxindol,



The action is remarkable in that only one of the carbonyl groups is attacked, a result that is perhaps due to the fact that isatin is more correctly represented by the formula



In this connection, it is noteworthy that a similar limitation is found in the case of phthalimide, a closely related substance, which may also be formulated in two ways as



AN article on air-resistance to plane surfaces is contributed to *Engineering* for March 10 by Mr. A. W. Johns. The pressure on plates placed normal to the direction of relative motion has alone been considered. Values of K in the formula $P=KAV^2$, where P is the pressure, A is the area, and V is the speed, have been tabulated in the article from the results obtained by many experimenters. Square, rectangular, and circular plates are included. Mr. Johns compares the various results, and arrives at the following conclusions:—(1) The value of the coefficient K for the same plate decreases as the speed increases. (2) For rectangular plates, the value of K for the same speed and area increases as the ratio between the lengths of the sides increases, and this increase is generally in accordance with Hagen's formula, viz.

$$P=AV^2(0.003+0.00004q),$$

where q is the ratio of the sides of the plate. (3) For similarly shaped plates the values of K are the same at "corresponding speeds"; that is, the "law of similitude" can be applied to the motion of plates through the air. This law asserts that for exactly similar bodies the dimensions of which have a ratio L, exactly similar phenomena attend the motions if the speeds have a ratio $\sqrt{L}$. For example, Dines' result for a 12-inch square plate at 40 miles per hour is $K=0.0029$. For a 60-inch square plate the "corresponding speed" would be $40\sqrt{\frac{60}{12}}=90$ miles per hour, at which speed K would have the same value, viz. 0.0029. Stanton's result for a 60-inch square plate is $K=0.0032$ for speeds between 0 and 25 miles per hour.

BULLETIN No. 44 of the University of Illinois gives account of an investigation of built-up columns under load, carried out by Messrs. A. N. Talbot and H. F. Moore at the University of Illinois Engineering Experiment Station. In the laboratory tests, the amount and distribution of the stress over the cross-section and throughout the length of the channels or other component parts of steel and wrought-iron built-up columns were investigated. The stresses in the lattice bars were also determined. Deformation of the channel members was measured by means of Ames test-gauges mounted on suitable frames. These instruments magnify change of length by means of clockwork operating a hand rotating over a dial. They read directly to 0.001 inch, and by estimation to 0.0001 inch. The deformation of the lattice bars of one of the columns was measured by Ewing's well-known extensometer. The stress distribution both with axial and with eccentric loading was examined. Similar tests were conducted on the columns of a railroad bridge under the load of a locomotive and cars. It was found that considerable local flexural action exists in the channel or angle members of columns. Marked changes in the stress distribution were found at cross-sections short distances apart. Stresses 40 to 50 per cent. in excess of the average stress were measured. The distribution of stress among the various lattice bars was very irregular. The results show the futility of attempting to determine the stresses in the lacing of a centrally loaded column from theoretical considerations. No relation was found between the stresses observed and the stresses computed by any of the usual column formulas. Copies of this bulletin may be obtained gratis upon application to W. T. M. Goss, University of Illinois, Urbana, Illinois.

THE Aëronautical Society of Great Britain will publish immediately, as No. 6 of the Aëronautical Classics, "The Flight of Birds," by G. A. Borelli, which first appeared in 1680. This study of bird-flight has been translated from the original Latin for the first time into English by the editors, Mr. T. O'B. Hubbard and Mr. J. H. Ledeboer, and includes a biographical notice and reproduction of the original diagrams and illustrations. The six "Classics," including Cayley, Wenham, Walker, Lana, Pilcher and Stringfellow, and Borelli, can be obtained separately in paper covers at 1*s*. net, or in one bound volume, with a specially designed cover, at 7*s*. 6*d*. net.

MESSRS. WITHERBY AND CO. have in the press an illustrated volume entitled "Photography for Bird-lovers," by Mr. Bentley Beetham. The book will be a practical guide to the pursuit of bird-photography in all its branches.

OUR ASTRONOMICAL COLUMN.

THE SYDNEY OBSERVATORY.—From an extract from the Sydney *Morning Herald*, reprinted in the March number of *The Observatory* (No. 433, pp. 117–8), we regret to learn that the State Government does not intend to act on the recommendation made by the Public Service Board, two years ago, that the Sydney Observatory should be removed to a more suitable site and properly reorganised. This observatory was founded half a century ago on a site which was then suitable, but which is now enwrapped by the dust and smoke of a great city, and its possibilities otherwise vitiated by the thick haze overhanging Darling Harbour. The instruments are obsolete, and Mr. Raymond, the officer in charge, has to perform his various

duties under great difficulties, and without the status, the authority, or the salary of a Government astronomer. The Public Service Board recommended the removal of the observatory to a more suitable locality, on an eminence not too far from the capital; the appointment of an astronomer with high scientific attainments at a suitable salary (800*l.* per annum and a residence); the re-equipment with modern instruments, including a large telescope of not less than 15 inches diameter; and that steps be taken to affiliate the observatory and the university. Whilst the latter recommendation has given rise to some difference of opinion, there is no dissension on the question of the necessity and advisability of re-establishing the observatory on a proper basis, so that New South Wales shall not be behind other States and countries in the prosecution of astronomical research. But the minds of the Ministers responsible are occupied with "important" matters!

THE SPECTRA OF SPIRAL NEBULÆ AND GLOBULAR STAR CLUSTERS.—On May 20, 1909 (vol. lxxx., p. 354) we directed attention in these columns to some interesting results, obtained by Mr. Fath at the Lick Observatory, concerning the probable structure of spiral nebulæ and globular clusters as indicated by their several spectra. A second paper by the same author appears in No. 1, vol. xxxiii., of *The Astrophysical Journal*, as a contribution (No. 49) from the Mount Wilson Solar Observatory.

For this later research Mr. Fath employed a spectrograph attached to the 60-inch reflector, and obtained spectra that are but little longer than 3 mm. between λλ 3700 and 5000; despite their small scale, these spectra afford further evidence as to the probable structure of the objects under consideration.

The spectrum of the spiral nebula N.G.C. 650–651 shows seven bright lines, at 373, 387, 397, 434, 486, 496, and 501 $\mu\mu$, corresponding to lines usually found in the spectra of gaseous nebulæ. N.G.C. 4725 gave a spectrum of the solar type with lines at F, G, H, and K, and a spectrum of N.G.C. 4736 is similar, with lines at F, G, 425 $\mu\mu$, 410 $\mu\mu$, H, K, and 387 $\mu\mu$. It is, however, a curious fact that the last-named spectrum differs considerably from one of the same object secured in the earlier research; the Mount Hamilton plate gave what was assumed to be a bright band at 406 $\mu\mu$, and absorption lines at 387 and 400 $\mu\mu$, but as it was not in good focus other plates will be taken with a new specially designed spectrograph which, it is hoped, will be constructed shortly.

Whilst recognising that the evidence is, as yet, slight, Mr. Fath suggests that these results point to a progressive change in the spectra of nebulæ with change of form. Starting with irregular nebulæ, like that in Orion, giving bright-line spectra, we pass to probable spiral nebulæ such as N.G.C. 650–1, where the spectrum shows bright lines and little or no continuous background, thence to planetary nebulæ, such as N.G.C. 6543, giving the bright lines and considerable continuous spectrum. In the fourth type the spiral form is well developed, *e.g.* N.G.C. 1068, and the spectrum, while still showing bright lines, has also a strong continuous spectrum, and contains absorption lines. The last type, exemplified by the Andromeda nebula, gives spectra of the solar type, and the nebula has condensed, at least partially, to stars. This progression indicates star-clusters as the final product.

The spectra of eight globular clusters are almost identical, of approximately the F type, in which the hydrogen series predominates, but, where the spectrum extends far enough, H and K are also found; a line, or band, near 419 $\mu\mu$ is also a common feature. In the Mount Hamilton plates, the Hercules cluster, N.G.C. 6205, gave evidence of the inclusion of more than one type of spectrum, but the more recent work does not support this; more plates with the slit crossing different parts of the cluster must be obtained.

THE DARK BORDERS OF THE MARTIAN SNOWCAPS.—In No. 4472 of the *Astronomische Nachrichten*, M. Antoniadi reverts to the question of the objective reality of the dark bands which appear to encircle the Martian polar caps. In a previous communication he maintained that, if real, they should show on photographs, but Prof. Lowell and others suggested that the brightness of the caps was so intense that the non-appearance of the dark areas might be accounted for by the photographic halation from the brilliant caps. This suggestion was supported by the statement that the photographs taken in America in 1909 showed the caps to be far more brilliant than the "continents." M. Antoniadi now brings independent testimony countering the statement, and maintains that the dark areas are not obliterated by photographic "spreading." In opposition to M. Jonckheere's contention that the dark bands exhibit the perspective they should do, if real, he states that he has never seen it, and reproduces a drawing made by Schiaparelli in 1884 in which the dark band is shown of equal breadth at the middle and at the ends of its major axis.

DOUBLE-STAR OBSERVATIONS.—Nos. 4479–80 of the *Astronomische Nachrichten* contain a large number of double-star observations made by Dr. Doberck at Sutton, Surrey. Most of the observations were made in 1910, and since 1910·13 the Elizabeth Thompson micrometer has been employed. In determining the scale value, corrections have been applied for aberration, refraction, and proper motion, and the final value obtained is $19{\cdot}342'' \pm 0{\cdot}002''$.

No. 6, vol. iv., of the Journal of the Royal Astronomical Society of Canada contains a number of double-star measures made by Mr. Motherwell with the 15-inch refractor of the Dominion Observatory. The work was commenced in 1907, the programme being to measure such pairs in Burnham's General Catalogue as are otherwise neglected or of which the motion seems uncertain.

THE "ANUARIO" OF THE MADRID OBSERVATORY.—The annual almanac published by the Madrid Observatory contains the usual tables and ephemerides for the sun, moon, and planets, and a number of extra tables, in which information as to the aspect of the sky, the azimuth of the pole star, and the passages of certain stars, &c., at given hours, is incorporated. Extensive tables for the calculation of latitude from observations of the pole star are also given, and the volume (1911) concludes with records of the solar and meteorological observations made during 1909.

THE NATIONAL PHYSICAL LABORATORY DURING 1910.

THE General Board of the National Physical Laboratory held its annual meeting at the laboratory on Friday last, March 17, when the report of the executive committee for the year 1910 was formally presented. As usual, a large number of visitors were invited, and were received by Sir Archibald Geikie, president of the Royal Society and chairman of the General Board of the laboratory, and by Lord Rayleigh, the chairman of the executive committee.

The reception this year took place in the buildings of the National Experimental Tank, where the equipment for the experiments to be undertaken on models of ships is now almost complete. The models, 20 feet in length, are cast in clay moulds, and shaped to the correct form by a special machine, which cuts in them a series of horizontal grooves, the operator guiding a tracing point over a corresponding sectional drawing. The wax is then trimmed down by hand to a smooth surface, leaving only the finest trace of the grooves as a guarantee of accuracy. The model is finally measured up on a special measuring table.

The carriage by which the model is towed along the tank weighs some 15 tons, and is driven by four motors designed to enable a speed of 17 miles an hour to be reached for the steady portion of the run. As is well known, the "model" law requires that the speed shall be proportional to the square root of the linear dimensions, and the speed indicated is therefore more than sufficient for the purposes of the tests.

The first report of the advisory committee for the tank appears in the report of the laboratory for the year 1910, and gives some interesting details of the construction, and, in an appendix, of the movements of the walls due to filling. A more complete account of the tank and its equipment, by the superintendent, Mr. G. S. Baker, will be presented to the Institution of Naval Architects at their meeting next month.

The visitors to the laboratory were also able to see the progress which has been made with the new buildings for metallurgy, for which the laboratory is indebted to the generosity of Sir Julius Wernher. In these ample accom-

modation will be provided in the near future for this important and increasing branch of the laboratory's work.

In the physics department, several interesting items of the year's work call for mention. The erection of the Lorenz apparatus, presented by the Drapers' Company as a memorial of Prof. Viriamu Jones, and constructed, by the kindness and generosity of Sir Andrew Noble, at the Elswick works of Sir W. G. Armstrong, Whitworth and Co., is now nearly completed. So far the running has been very satisfactory, the speed remaining constant within 5 parts in 100,000, without regulation, for fifteen minutes. Only the marble cylinders on which the coils are wound now require to be put into place.

In April and May, 1910, Mr. F. E. Smith visited Washington, as the representative of the laboratory, to take part in an international research on the silver voltameter and the Weston normal cell. A full report on the work will shortly be presented to the International Committee on Electrical Standards, which was constituted at the London conference of 1908. The immediate result of the work has been the adoption of the value 1·0183 international volts, in place of 1·0184, as the electromotive force of the Weston normal cell (see NATURE, February 16, p. 508).

The valuable researches on the construction and accurate measurement of inductances, which have now extended over several years, have been continued; an interesting feature of the recent work has been the construction of a resistance box of constant and almost negligible inductance. A comparison of magnetic tests, for total loss, on steel sheet is in progress, in cooperation with the Bureau of Standards at Washington and the Physikalisch-Technische Reichsanstalt.

The electrotechnics division has made investigations into the effect of travelling on supply meters, the heating of lamp sockets, the electric strength of micanite, and into the deterioration, and possible means of protection, of ebonite surfaces, which all present matter of considerable practical value. Tesfs on the heating of cables have been carried out for the Wiring Rules Committee of the Institution of Electrical Engineers. In photometry, the establishment of metallic filament sub-standard lamps has required an investigation which has presented numerous difficulties, and furnished results of much theoretical and practical interest. An important comparison of life tests of glow-lamps was carried out between the laboratory and the Electrical Testing Laboratories of New York, and showed that agreement within 5 per cent. could be expected in such tests.

In the work on the fundamental high-temperature scale, difficulties have been met with in the construction of the reservoirs and tubes of refractory rare-earth materials, which for the time have delayed progress. Valuable work has been done for the International Commission which is dealing with the methods and apparatus for petroleum testing. It is well known that different forms of flash-point apparatus give different values for the flash-point of an oil. Careful exploration of the temperatures below and at the oil surface, and in the vapour, up to the time of flash, has indicated a probable cause of these discrepancies. Some interesting tests have been carried out on the Siemens' calorimetric water pyrometer.

In the metrology division, Mr. J. E. Sears has taken over the charge of the work from Mr. H. H. Jeffcott, who was appointed early in 1910 to the professorship of engineering in the Royal College of Science, Dublin. An interesting feature of the year's work has been the study of the thermal expansion and hysteresis of fused silica, in connection with the new silica standard of length. An account of this work, and of a method employed for counting the rulings of a diffraction grating, has been prepared by Dr. Kaye, and published in the *Philosophical Magazine.*

In the optics division, a tilting table of special design has been installed for tests on clinometers and levels, and metal prisms to serve as standards of angle have been made for use with it, their angles being measured by optical means to a high degree of accuracy.

In the engineering department, a large number of researches have been further advanced, among which may be mentioned specially the investigation into the strength and efficiency of welded joints, the work on alternating stresses of high frequency, shock tests on different forms of screw threads, and the research on the heat transmission and friction of air currents in pipes. In the aëronautics section much interesting work has also been done. The investigations in the air and water channels have dealt with the resistance, stability, and fin area of dirigibles, the lift and drift and centre of pressure of curved surfaces for use as rudders or for other purposes, the resistance of wires, stationary and vibrating, and of ropes, as well as of radiators, model gondolas, &c. The propeller test results have been improved by a careful investigation of the motion set up in the air of the whirling-table shed due to the motion of the whirling arm. The tests of motors entered for the Alexander prize, together with the construction of the necessary testing plant, also formed an important feature of the year's work. The report on these tests was published in November last.

The chief metallurgical research concluded during the year 1910 was that on the aluminium-copper-manganese alloys, which formed the subject of the ninth report to the Alloys Research Committeee of the Institution of Mechanical Engineers. Work on the alloys of aluminium and zinc has since been in progress, and an interesting paper on the theoretical results of this research has recently been communicated to the Royal Society. The investigations into the eutectic alloys, and into the effect of strain on steel at high temperatures, have also made good progress. The planning of the new metallurgical laboratories has, of course, constituted an important part of the year's work.

The section of the report which deals with the work of the observatory department gives details as to the tests of instruments during 1910, and also some particulars of the growth of the Kew verification work between 1880 and 1910. The number of "clinicals" tested in 1881 was about 4000, in 1909 nearly 26,000. The total number of instruments tested since 1880 is more than 673,000. In July last the meteorological work of Kew was transferred to the Meteorological Office, of which Kew will in future be the central observatory.

The complete scheme of reorganisation of the Kew work involves the transference to Teddington of the instrument testing, but for this increased accommodation at Teddington is necessary. The great growth of the work of the laboratory renders also imperative the provision of a building for office and administration purposes. The plans for these additional buildings are already well advanced, and it is earnestly to be hoped that lack of funds will not be allowed to hamper and to curtail the natural development of the important work which the laboratory is called upon to undertake. Figures published in the laboratory report for 1910 show that, out of a total capital expenditure of about 103,000*l.*, 49,000*l.* is due to Government grants, while 54,000*l.* has been received from private sources and as payment for work done; and in view of these figures the committee urge that the request for funds for the much needed extension is one which deserves most favourable consideration from the Treasury.

The preceding paragraph is based on the report of the executive committee of the laboratory to the general board. We understand it was stated at the meeting that an intimation has just been received from the Treasury that the sum of 500*l.* will be placed on the Estimates for 1911–12 towards the cost of the new buildings proposed. The recognition thus afforded of the importance of the work which the laboratory is doing is valuable, but the sum is clearly insufficient to enable the scheme which has been prepared, the estimated expense of which is about 20,000*l.*, to go forward immediately. It is, of course, possible that some other generous donor may be found ready to assist the laboratory in its national work; the electrotechnics building was provided by a gift of 5000*l.* from Sir John Brunner, Mr. A. F. Yarrow has enabled the national experimental tank to be constructed at a cost of 20,000*l.*, and, as already stated, Sir Julius Wernher has recently given 10,000*l.* for the erection of the metallurgy building, while others have given large sums towards the equipment of the laboratory. It is to be hoped that the Royal Society and the governing board of the laboratory may find means which will enable them to provide, without unnecessary delay, the additional buildings and accommodation rendered necessary by the rapid development of the work.

VELOCITY OF EARTH MOVEMENTS CAUSED BY THE MESSINA EARTHQUAKE.

TO the *Reale Accademia delle Scienze di Torino* (1909–10, p. 355) Prof. G. B. Rizzo has contributed an interesting paper on the velocity with which earth movements occasioned by the earthquake which ruined Messina on December 28, 1908, were propagated to different parts of the world. First he gives in detail the observations made with various types of seismographs at 110 stations. These he sums up in tables, which show for the preliminary tremors or P_1, their followers or P_2, and the large waves or P_3, the time taken by them to travel from their origin to these various stations, their average superficial velocity, and the velocities with which the two first types of movement may have passed along paths corresponding to chords. The first results are also shown as curves drawn on squared paper, the two ordinates, respectively, referring to time and distance. The greatest distance considered is 10,000 kilometres, or 90 degrees, although the tables give results to distances exceeding 18,000 kilometres, or 163 degrees. Dr. Rizzo remarks that none of these curves show the flexure near the epicentrum which Schmidt, like Seebach, has used to determine the depth of the hypocentre. The absence of this is taken by Dr. Rizzo to indicate that the origin of the Messina earthquake was very shallow, a conclusion which I do not think will be shared by all seismologists. Many seismologists will, however, agree with him when he bases the idea of a shallow origin upon the comparatively small area of destructivity.

Up to a distance of 1500 kilometres from the epicentre the velocity of all three phases of movements is constant. The inference from this is that up to such a distance the movements are propagated within the crust of the earth, which is estimated as having a thickness of 44 kilometres. From this distance there is a marked increase in the velocity of the first phase, which, however, is not shown by the succeeding phases. The third or large-wave phase he divides into three parts, which he calls L_1, L_2, and L_3. L_1 appears to correspond with the commencement of maximum motion, whilst L_2 is the maximum movement itself. L_3 is the phase which travels the slowest, but if this is to be accepted as a definite and a recognisable phase in a seismogram, there seems to be no reason why we should not also accept very many other phases, which might be indicated by the letters L_4, L_5, L_6, &c.

Of late years, very many hodographs of the character of the one now presented to us by Prof. Rizzo have been constructed. Prof. H. F. Reid has given us an excellent set of time curves relating to the San Francisco earthquake of 1906. Up to a distance of about 55 degrees from the origin these indicate velocities somewhat higher than those given by Prof. Rizzo, but beyond that distance they are very similar. This kind of difference which we find in the work by different seismologists may be due to differences in the manner in which they have interpretated seismograms, but it is much more likely to arise from the non-recognition of all the elements which should be considered when carrying out these particular investigations. J. MILNE.

THE EBRO OBSERVATORY OF COSMICAL PHYSICS.

EL OBSERVATORIO DEL EBRO is situated in Roquetas, near Tortosa, on the river Ebro, Spain. It is in latitude 40° 19′ 14″ N. and longitude oh. 1m. 58·5° E. Its altitude is 51 m. Originally of private origin, it was inaugurated in September, 1904, in connection with the Collège d'Etudes Superieures de la Compagnie de Jesus, Tortosa, with the assistance of many private individuals. In October, 1904, it was recognised by the Spanish Government as an establishment of public utility, and, following this, the Government in 1907 made a grant in aid, which is used to defray the cost of the publication of memoirs and bulletins.

The observatory consists of eight separate buildings, and observations are made in meteorology, solar physics, terrestrial magnetism, electricity, and seismology. An account of the observatory, and also of the observations of the total solar eclipse of 1905, is contained in the first memoir, written by the director, Padre R. Cirera, S.J. The second, third, and fourth memoirs are entitled, respectively, "La Observacion Solar," "La Seccion Magnética," and "La Seccion Electrica."

In the solar section, daily photographs of the sun are taken both in integrated light by photoheliograph and in "K" by the spectroheliograph, which is of the Evershed type. This instrument gives a disc of 62 mm. diameter, the primary image being formed by an objective of 150 mm. aperture and 2 m. focal length.

The areas and positions of spots, on the heliograph pictures, and of the flocculi, on the spectroheliograph negatives, are measured and published in the monthly bulletins.

In the meteorological section, all the usual observations of pressure, temperature, rainfall, winds, and clouds are made with well-known standard instruments three times a day, viz. at 7h., 14h., and 21h.

The observations of atmospheric potential, ionisation, &c., are undertaken by the meteorological department. In the department of geophysics, the observations of magnetic values and variations are made, and hourly values are tabulated. A microseismograph "Vincentini" and a "Grablovitz" pendulum are used in the seismological section. The results of all these observations, both tabular and curves, are published in monthly bulletins.

The first bulletin is for January, 1910, and those for February, March, and April have also been published. The January bulletin contains a short account of the observatory, and accounts also of the methods used in making and reducing the observations.

Having regard to the amount of work which each bulletin represents, and noting the convenience of having all the different elements registered in one volume, the director, Padre R. Cirera, S.J., is to be congratulated on having been able to issue them so shortly after the making of the observations. M.

EMOTION AND MORALS.

ON Saturday afternoon, March 11, a meeting of the British Psychological Society was held at King's College, London, Mr. A. F. Shand in the chair, when Dr. William Brown read a paper on "Emotions and Morals." After a brief survey of the views of earlier writers on the nature and classification of the emotions and their relation to ethics, in which, however, the doctrines of Aristotle and Adam Smith ("Theory of Moral Sentiments") were treated at some length, the author proceeded to discuss the meaning of the terms "passion," "emotion," and "sentiment" in relation to the theories of Ribot, Shand, and McDougall. According to ordinary uses of the term, and also to its etymology, passion would seem to indicate an uncontrollable state of mind, in the form either of an actual emotion or a system of emotional tendencies. Although Shand's employment of the term sentiment to express the conception of "a system of emotional dispositions centred about the idea of some object" would theoretically cover the latter of these two uses, passion seems to be a more appropriate and expressive word to indicate those systems which are uncontrollable by the rest of the mind, and issue, under appropriate conditions, in uncontrollable emotions, *e.g.* "a passion for politics," "a passion for the stage."

The word sentiment, as used in literature, has acquired associations of weakness or placidity which constitutes a slight drawback to its use in scientific psychology to cover all cases included in the technical definition of Shand above-mentioned. "Tender emotion," identified by Ribot and McDougall with the parental instinct, seems to have a wider connotation, and receives more adequate treatment from Shand. In particular, the element of tenderness or pathos present in many æsthetic emotions has little connection with the parental instinct.

The question of "emotions and art" was treated at some length, with special reference to music and the drama. Neither the sensationalistic nor the formalistic theory is adequate as an explanation of music. The ancient Greeks were right in regarding music as "the proper language of the emotions," but it is important to realise that the emotions of music are not, strictly speaking, identical with the emotions of everyday life. They

are analogous to the latter, and this explains the appropriateness of the music to the words in opera, but they really belong to a world of their own and possess a meaning of their own. This is why the music of an opera, even when entirely appropriate to the words, may transcend them in such a way that elements of grossness in the story entirely lose their real "work-a-day" significance in the total presentation. The "Salome" of Strauss is a striking illustration of this.

As regards the psychology of acting, the important statistical investigation carried out by Mr. William Archer, the dramatic critic, more than twenty years ago, is the only work of definite scientific value hitherto produced. Mr. Archer's chief purpose was to test the paradoxical view of Diderot, accepted by Coquelin, but rejected by Sir Henry Irving, that stage emotion should not be real, and that the really first-class actor should be a man of little or no "sensibility." The results showed that in almost all cases of first-class acting in England, not only did the principal signs of real emotion—real tears, blushing, pallor, &c.—occur, but the artists experienced genuine emotion, and often found real emotion from their private lives help them on the stage by mingling with and intensifying their feigned emotion. A state of dual consciousness while acting was found to be common, but not universal.

Mr. Archer adds many further comments of considerable psychological value, and predicts that the subject will be taken up some day by trained psychologists and subjected to an exhaustive discussion.

As an illustration of many of the points raised by Mr. Archer, a letter very kindly written by Miss Ethel Irving as a reply to a query as to her state of mind when playing intense emotional parts, was quoted and discussed, and a general theory of stage-emotion was sketched out and illustrated by a brief description of Miss Irving's recent emotional acting, especially in Henry Bataille's play, "Dame Nature."

GREEK LANDS AND THEIR PEOPLE.[1]

THE establishment by the University of Oxford, from resources supplied by New College, of a new chair for the exploration of ancient history obviously requires, in view of the facilities which already exist for the study of the subject, the justification which is supplied in the inaugural address delivered by Dr. J. L. Myres, the first occupant of the Wykeham professorship.

Dr. Myres justly remarks that, up to the present, the historical course has been too largely devoted to the centuries adjoining the fifth; that it has too jealously confined its researches to the ascertained results of earlier inquiries; that it has discouraged novel methods of investigation; that, in short, its work has become stereotyped and unenterprising. In pointing out a more excellent programme of research, he directs special attention to what may be termed the economic geography and biology of the peoples of the Eastern Ægean. Much has already been done on these lines of research, as in the cartography of Curtius and Kaupert, the examination of battlefields by experts in the art of war, M. Berard's application of sea-lore to Homeric geography, the study of the influence of malaria on the decay of nations, and, lastly, Mr. Huntingdon's investigations of historic meteorology. But much still remains to be done towards exploring the effects of environmental control on the course of history.

The modern Greek race, it is admitted, is largely intermixed with Albanian, Vlach, and Levantine elements. But this fusion of peoples has been continuous from primitive times, so that the history of the Mediterranean area is, as a whole, a history of its invasions, the earliest sea-borne settlers being of the "Mediterranean" reinforced by "Alpine" and "Armenoid" types. But amidst these racial movements, the mountains, the sea, the climate, the flora, have been there from the beginning, and the ethnological situation now depends not so much upon race as upon the prepotent influence of the environment. "No type of non-Mediterranean invader has ever learnt so quickly how to live under Mediterranean conditions as to escape extinction in the process"; the "external environment modifies breed in Man by offering the alternatives of extinction or conformity."

This environment falls into at least three types. First, the prevalence of scrub-lands results in the smallness and discontinuity of the Mediterranean populations; there is little produce from this area, and so "the Greek world is in general a jamless world"; there is little sport except in the mountain region; the cow and the horse are "oasis animals, fed almost by hand." In the forest region the conditions are more propitious, the olive, grape, orange, and lemon providing considerable sources of revenue, while the goat furnishes the milk supply, and the pig is as important as it was in the household of Ulysses. On the other hand, the ubiquitous, restless goatherd is a constant source of political confusion, while the almost exclusive employment of women and children in the collection of forest produce tends towards the growth of the matriarchate.

Secondly come the grasslands, and the relation of the pastoral races to Ægean culture, leading on to the third type, that of the agriculturist, of which the leading characteristic is the crowding into the season between March and July of processes which in more northern lands extend to October, thus leaving one of the busiest seasons of the English year to idle hands "devoted to the devil's work of seasonal war."

The programme of the new chair thus promises an attempt towards the solution of the ethnical problems of the Ægean on new and scientific lines; and though the address of Prof. Myres is not free from certain characteristic foibles of the Oxford school, anthropologists will readily admit that no more competent and imaginative scholar could have been selected to hold the Wykeham professorship.

[1] "Greek Lands and the Greek People." An Inaugural Lecture delivered before the University of Oxford, November 11, 1910, by Prof. J. L. Myres, Pp. 32. (Oxford: Clarendon Press, 1910.) Price 1s. 6d. net.

A DESTRUCTIVE DISEASE OF POTATOES.

A VERY interesting and valuable report on "Wart Disease of Potatoes" has been issued by the Harper Adams Agricultural College. As in the case of previous reports on the same subject, the cost of publication, and also expenses connected with garden trials, have been borne by Mr. Beville Stanier, M.P.

The present report brings together a number of facts which, taken together, show the magnitude of the danger now threatening potato-growing in Great Britain. The comparatively new and most destructive fungous disease known as "Wart Disease" was first reported in Shropshire in 1901 in the Woore district; by 1908 it had assumed alarming proportions in this and other counties —facts which are here emphasised by some admirable maps. The extent to which the disease has now spread in Great Britain is shown by one of these maps, in which a continuous belt of affected counties stretches down the west side of Great Britain from Perth to Glamorgan—no fewer than thirty counties being affected. In the majority of these counties the disease is confined, as yet, to gardens and allotments (the soil of which in some cases has become so contaminated that it is impossible to grow potatoes profitably), but the authors of the report very rightly lay stress on the fact that the risk of the disease spreading from these centres of infection to the fields of farmers is very great. A perusal of this report, indeed, must convince the reader that this disease—which the Vice-president of the Irish Department of Agriculture referred to last year in the House of Commons as "that terrible disease known as 'Black Scab'"—must now actually be spreading to farm-lands in many counties in England and Scotland, as has already happened in Lancashire and Cheshire.

An instance is given of a consignment of seed potatoes (obtained from a county where the disease is very prevalent) which, distributed for use as "seed," gave rise to a number of outbreaks extending over a five-mile radius. The disease is spread also by animals; cases are here recorded where trespassing pigs and poultry have carried the fungus to clean ground and caused outbreaks of the disease. The use of manure from animals (especially pigs) fed on raw "warty" potatoes is a common means of

distribution of the disease with regard to cottage gardens. Workmen who have used spades in digging in infected soil have, when planting potatoes in clean ground, carried the disease on these tools.

Trials of a large number of fungicides have failed to discover any of value. With regard to the behaviour of different varieties of potatoes to the disease, it has been found that all the best and more generally grown varieties, such as Up to Date, British Queen, and allied sorts, are very susceptible. In the "variety tests," however, marked resistance to the disease has been shown by a number of other varieties (Langworthy, Golden Wonder, What's Wanted, &c.).

A clear account of the life-history of the fungus is given, and the new fact reported that the development of warts continues during winter months in stored potatoes. The various plates published with this report are unusually good.

E. S. S.

PROFESSORS AND PRACTICAL MEN.[1]

AFTER allusions to a boyhood spent among practical men, to subsequent university life in Great Britain and Germany, and to the tendency of English men of science with such experience to extol the German system and recommend its adoption, Prof. Smithell's proceeded as follows :—

I am sure that, among the class to which I belong, there is a danger of underestimating the deep-seated powers of Englishmen, of neglecting the true genius of our countrymen, and, in short, of falling into a narrow-mindedness which tends to put us out of sympathy with the people we desire to serve. I think that no one who has studied the history of our industrial development, or has moved observantly among our industrial community, can have failed to be impressed by the great native capacity of the Englishman for practical affairs. The quality is one exceedingly difficult to define. It is very elusive; but it is there—this power of doing things—a power compounded of energy, shrewdness, enterprise, determination, sense of the fitness of things, and knowledge of the intuitive kind. Who does not know the man who, somehow or other, can get hold of the right thing; knows a good thing when he sees it; has an unerring sense of a wrong thing; knows when and where to buy a thing, when and where to sell a thing—who, in short, does not know a good craftsman; and where in the world will you find a better than in England? I honestly believe —nowhere. And yet it may be said that a man who is this, and no more than this, is but a "serviceable savage." I do not agree. He is a man who has developed one set of faculties; but it is a set by no means to be disparaged, by no neglect to be allowed to rust. I honour the man in his workshop who can tell by the look, the feel, the sense of a thing, what it is good for, as well as I can tell by the light of science from the intellectual eminence of a university, for I know that if he is really first-rate in his way, he can assess the value of things for which my science has yet no touchstone. It will be, I dare say, many a long day before an epicure can choose his vintage by chemical analysis; it will certainly be long before science can fully supplant the finely cultivated instinct of the true practical man.

I trust, therefore, gentlemen, that if I, a mere man of science, take upon myself to talk to you about education in relation to your own pursuits, I do not neglect that vastly important element, of education, that development of "mother wit," which comes to man as he fulfils his appointed task of wrestling in the world with men and things for his survival among the fittest. I am not going to emulate the action of a learned acquaintance of mine, who has recently taken upon himself to lecture the pioneers of aviation because they have not delayed their heroic enterprise until the mathematicians have discovered the true theory of stability. Scientific men of this kind, if they had their way, seem to be most likely to achieve the true practice of stagnation. I do not bid you cease to lay mains, to erect gas-holders, or to make gas-fires until we in the august seclusion of our learned halls have worked out the whole true science of heating and illumination.

It is, however, man's prerogative, and it should be his delight, to possess, to use, and to extend the faculty of reason; to increase his power over the forces of nature, and constrain them to his service by a deliberate, a carefully organised, and an unceasing cultivation of the human mind. The true barbarian is the man who is content to do, and does not want to know; and yet how many men are there not, whom no one could call barbarians, who look upon our system of education with a degree of distrust that increases in intensity as their survey passes upwards from the elementary school to the university? This, in my judgment, is a most serious question of the day.

I have long held the opinion that education in England is afflicted from top to bottom with an utterly exaggerated fear of what is called useful knowledge. In that fear, much of a vital kind has been left undone, and much has been given in the name of education which helps its possessor neither to truer wisdom, better work, nobler conduct, nor to greater happiness. The world cries out for educational bread, and it receives only too often an academic stone.

I do not know that I am behind other men in the delight I feel in abstract studies, and I can honestly say it is but rarely I envy another man his larger share of loaves and fishes; but knowledge gathered for what is sometimes called its own sake, and treasured for its own sake, seems to me in great danger of unwholesomeness, and a learned man, who is merely a man of erudition, to be as likely to prove a mischief as he is certain to be a bore.

At the head of our educational system stand the universities. A university is, or should be, in essence a mine and a mart for the highest learning. It was in its origin an adjunct to those callings which made the greatest demand upon the powers of thought. You may put it more picturesquely, no doubt, but it suits my purpose best to use homely terms, for I believe too little stress has been placed upon the real beginning and the original purpose of universities as institutions standing in direct relationship to definite callings. It is, I believe, because our university system has not kept pace with the great changes that have taken place in the character of human occupations, that universities have failed to secure or to retain the sympathy of a large section of the community. The great delay in the development of research and instruction in natural science in the universities led to a corresponding delay in the dissemination of elementary scientific knowledge through our schools, and in consequence we find to-day in the older generation of our more educated citizens, to say nothing of those less educated, a whole legion of men whose knowledge of science would not correspond in terms of their grammar to knowing the difference between a noun and an adjective, in their geography the difference between latitude and longitude, and in their Latin to that between Cicero and Cæsar.

Now I lay great stress upon this lack of the general dissemination of scientific knowledge, because people sometimes say to me that, after all, we have surely had many distinguished men of science in our universities for generations past. It is true; but they were not preparing a market for their wares; they were elaborating in their seclusion something which was utterly mysterious to the average man. Even to-day people come occasionally into my laboratory with the air of men entering a hall of mystery or a chamber of horrors, fearful of what may befall them. Again, people say to me, surely the industrial fruits of scientific knowledge have long been recognised. True again, most palpably true; but how the fruit is related to the knowledge, how the seed is sown, how it is tended, what should be done to nurture the plant, that is not known. It is not known because your educational system did not achieve this one thing for the community—it did not put its victims for a single occasion in their lives in the position of asking a simple scientific question and of faithfully finding the answer by experiment.

Now the portion of knowledge which most completely and vitally interpenetrates our manufactures is natural science, and it has been, I think, an incalculable dis-

[1] Presidential Address to the Society of British Gas Industries, delivered at the annual meeting held in Leeds on March 3, by Prof. Arthur Smithells, F.R.S.

advantage that, whilst these manufactures were advancing by leaps and bounds during the century succeeding the industrial revolution (which I suppose may be dated about 1760) there was no movement in the educational world for a general dissemination of scientific knowledge and skill. During that period several misconceptions took deep root in the English mind. The achievements of Arkwright the barber, Hargreaves the weaver, Crompton the farmer, Watt the instrument maker, Cartwright the clergyman, Stephenson the fireman, Murdock the millwright, and of all that illustrious group—their great and fundamental achievements created an overwhelming belief that the self-taught inventor was destined to be the only important pioneer in industrial discovery, and to this day a young man brought up on a diet of grammar and Samuel Smiles might well despair of contributing anything of moment to the service of industry, unless, indeed, he happened to be exceptionally poor and to have attended no more showy a place of education than a night-school.

If the universities had set themselves to send a current of science through our schools at the time when the direct utility of scientific knowledge and of scientific method was becoming demonstrable in the industrial world, we should, I think, be in a very different position to-day, and our universities would hold a very different place in the esteem of our countrymen. It is this historical retrospect, and the experience of the frantic and wasteful struggles in my own lifetime on the part of the worker to come to terms with the thinker, that have made me realise the dangers that attend academic seclusion, and have left me well content that my lot as a university teacher is cast within ear-shot of the throb and hum of busy workshops.

Of all that we have lost in the course of the events I have described, nothing is more difficult to retrieve than confidence in the practical usefulness of university science. We are suspected at every turn of trying to elude the practical man, and to betake ourselves to studies and impart information the glory of which lies in its detachment from all things mundane and remunerative. We have engendered the suspicion that we are intellectually exclusive, and that we do not understand, or sympathise with, the practical point of view. A better understanding between us is, I think, a matter of the greatest national importance, and it has seemed to me that if a better understanding is to be attained, it is incumbent on the universities to go out so far as ever they can to meet the legitimate claims of the industrial community, and to bring their studies deliberately into the closest possible relationship with the industrial arts.

I think I may claim that in this university we have shown no lack of courage in doing so. In spite of a good deal of academic apprehension and distrust, not always kindly expressed, from outside critics, we have established departments of work for the explicit purpose of furthering the special pursuits of industry, much in the same way and in the same spirit as schools of law, medicine, and theology were established in bygone days.

Another thing, on which I would lay the greatest stress, is that we have secured in the direction of our university as a whole, and of these special departments in particular, the active cooperation of men of business and of representatives of the particular industries concerned. I do not look upon these steps as a gracious concession, still less as a sordid opportunism. I believe they secure the best interests of thought as surely as I hope they will serve the most immediate needs of work.

No one who has studied the history of science can be ignorant of the fact that science has its roots and has gained its greatest impulse in the practical avocations of mankind. Chemistry was born in foundries and pharmacies, and nearly every great advance can be traced to some industrial impulse. I suppose the greatest achievements in chemistry were those of Lavoisier. How did they arise? I believe I am not wrong in saying that it was in the preparation of his prize essay on the best mode of lighting the streets of Paris. Beginning with a consideration of the best form of lamp, the most effective form of reflectors, the most suitable shape of oil-containers, Lavoisier passed to the study of combustion, and finding organic things like oil and tallow too complex to reveal the fundamental nature of the process, he betook himself to simpler things like phosphorus and zinc, and so was led to the train of discoveries which constitute the foundations of modern chemistry. "It was," as M. le Chatelier has said, "this constant preoccupation with practical questions that enabled Lavoisier to escape without effort from the fictions and conventions amid which contemporary chemists were merely marking time."

I have given you but one of innumerable examples to illustrate a truth that we who profess science should never be permitted to forget, and to assure you that I regard the close association of universities with the business world as of enormous advantage to the universities. We have in this, I believe, the true corrective of academic excesses, the best stay for academic frailties; and I believe the good understanding and mutual respect which we may hope to bring about between the leaders in the spheres of labour and of learning will be extended rapidly through the rank and file.

I hope you will find in what I have said so far, the evidence of a desire to acknowledge some of the short-comings of the academic world. But I might well be suspected of having had my head turned by the dignity you have conferred upon me if I left you under the impression that I thought the faults were wholly on one side. In what remains of the time at my disposal I wish to confide in you some of the difficulties of the situation which arise from the other side.

I believe that a very large number of business men go wrong when they enter upon the consideration or criticism of educational affairs by attempting to apply methods and standards and principles borrowed from their own callings, which, however excellent in their proper place, do not apply, or at least do not apply in the same way, to education. Let me remind you, in the very first place, that you can, for example, prepare no balance-sheet of a university. You know how much money comes into the university chest and how much is paid out, but how much a university costs or how much it earns no man can discover. Suppose, for example, in my zeal to find employment for a student, I send you a young chemist who, by his unrestrained ardour or incompetence, misleads you into all kinds of futile extravagance, surely you would debit that to the university. I do not doubt you would. Every care is taken that such things are brought home to us. Suppose, on the other hand, I send you someone, like a former student I met last week, who, by what he had learned here, increased the output of his employer's business by 33 per cent. Should that not be credited to the university if by someone's indiscretion you happened to hear of it? I think so. In a business like ours it transcends the powers of any accountant to effect an audit; you would need a whole secret service of educated spies. You, individually, may give us a thousand pounds in the hope of a return, but you, individually, may get nothing in return—at least in this world—or you may get a return that you cannot trace to its source. No; the essence of university finance is collective investment. It is, to some considerable extent, selective for a locality, and may be made equally so for a single group of interests or industries; but, looking at a university as a whole, it is national, or even international, in its financial ramifications.

If I and many of my colleagues in this and other universities are of some value to this country, I would have you remember that the cost of our education has to a quite considerable extent fallen upon the German tax-payer.

If I say that the students who have gone from our chemical department are collectively earning half a million a year for the firms who employ them, no one can contradict me; and I am tempted to affirm it positively as a counterblast to those hasty financiers who look at our accounts and raise their voice in lamentation over the capital we lay down, without stopping to think of the unrecorded dividends that accrue.

I will take another thing. I think a good business man, whilst anxious to progress and branch out, whilst ready to take risks and go somewhat afield for promising expedients or appliances, is usually very careful not to lose sight of the main current of his affairs, expecting to profit by deliberate methodical plans rather than by totally unexpected accidents.

The same is doubtless true within the pursuit of science

itself, where the object is simply to elucidate a given problem. But when it comes to the contact between science and industry, an entirely new factor appears.

The discovery of the atmospheric burner was not an accident. It arose from the desire of Bunsen to have a gas flame that would not smoke his flasks, and it was contrived by a stroke of genius. But what an accident for you that a man of genius should want a smokeless flame! When I was a student in Bunsen's laboratory there came to it Carl Auer von Welsbach, in the spirit of an unalloyed philosopher, eager to solve some problems about the group of chemical elements that seemed, of all, the most remote from any daily human needs. He noticed the remarkable glow of the mixed oxides when a flame impinged upon them, and so begat the mantle. Again, I say, no accident for him; but, again, what an accident for you, that a man of genius should want to investigate the mystery of rare earths!

I need not ask you where the gas industries would be to-day without these windfalls from the tree of scientific knowledge, the scientific branches of which, be it remembered, wave most vigorously in the upper air. By what definite planning are you to get discoveries of this kind made? The answer is, I think, by treasuring your men of genius and letting them work in the light of their genius. Surely the time has gone by to wonder whether true scientific work, carried on in the spirit of a philosopher by a man of genius with his feet upon the earth, subserves the material needs of humanity. Who is there that will dare to set his finger on any patch of new natural knowledge and say: "This may be edifying, but it is nothing to us"?

When, therefore, you seek to bring science into your service, beware of unduly fettering the minds and discriminating the topics. This seems to be the hardest lesson of all for the Englishman to learn. His very straightforwardness and stern common sense, his businesslike ways, may all conspire to make him unbusinesslike in matters of education and research, to which, believe me, a man must serve a long apprenticeship before he becomes a master craftsman. I will listen eagerly to a business man whilst he tells me what he wants; I will eagerly seek the real knowledge that he has to give; I will eagerly lean upon him in the manifold business of administration; I will eagerly take his money; but when he wants to tell me that I shall teach this and not teach that, that this is useful, the other useless, above all, when he talks as if a well-constituted university should give proficiency in the practice of trades and render apprenticeship superfluous—well, I do not listen to him very patiently, and I say to myself, "Alas, that this man should think himself practical!"

If we on our side come to take a more sympathetic and direct part in bringing science to your service, I plead that you on yours shall show a larger measure of faith, of hope, and, I might almost say, of charity. Do not try to constrain us in our own proper business; do not be impatient of returns. They are sure to come; history has abundantly proved it; but you must freely cast your bread upon the waters.

I have chosen in this address to take what may be called a materialistic view of education, and I am not ashamed. I do not forget that education has many purposes to serve, and that man does not live by bread alone. But without bread man becomes a shadowy or a rebellious being, an ascetic or an anarchist. He must have bread, and he must get it by the sweat of his brow. Englishmen collectively must have work, the nation must have industries, and I take it as no degradation of education to contrive that it shall minister directly to their preservation, their progress, and their prosperity. Rather would I say this—that thereby you dignify labour, refresh the toiler with the fruits of knowledge, and infuse into his daily work the delight of seeing beneath its grime and dust a play of stupendous forces within majestic laws.

Of all the men whom I have known, I could point to no one who, more completely than George Livesey, embodied the finest native strength of the English industrialist. He was one of those men to whom I referred at the beginning of this address, and was bound to succeed independently of all that we call formal education. But you know that he never breathed any such vulgar boast. On the contrary, he believed with all his heart in the worth of all things intellectual. He was eager to draw to his aid all the resources of modern science; he took the broadest, most sympathetic, view of scientific research, and I can, as I have said before, imagine no memorial more acceptable to him than the one which, to our great honour, you have set up in this University. In the inspiring address which he delivered to you from this chair three years ago, he lifted your thoughts to the ethical side of industrial life, and preached to you the chivalry which you knew he had practised in his life. Honest dealing, confidence between man and man, care for the workman, national before personal interests—in short, a large-hearted humanity—these were his topics as they were his qualities. I am not without hope that in the universities, old and new, where knowledge should be cultivated, whatever it may pertain to, in the worship of truth, where young men should see visions, we may help to maintain the fine flower of British industry of which George Livesey was so splendid an example.

VISUAL SENSATIONS FROM THE ALTERNATING MAGNETIC FIELD.

FOLLOWING on the experiments reported by Prof. Silvanus P. Thompson in the Proceedings of the Royal Society, B, 82 (557), pp. 396 ff., it is interesting to note the further research in this subject pursued by Mr. Knight Dunlap, an account of which appeared in *Science* of January 13.

Prof. Thompson subjected the head to the influence of an alternating magnetic field, which was obtained by means of a coil of thirty-two turns of stranded copper conductor having an internal diameter of 9 inches and a length of 8 inches. The coil was supplied with a current the maximum value of which was 180 amperes at a frequency of fifty cycles per second.

On inserting the head in the coil under these conditions, a flickering light sensation was obtained, the sensation being more clearly defined in the peripheral part of the field of vision.

The object of the further experiments by Mr. Dunlap was to ascertain whether or not these sensations were due to idio-retinal light, under the suggestion of the hum of the coil caused by the alternating current.

A coil was constructed which gave a field of approximately the same density as that obtained by Prof. Thompson, and identical results were observed.

In order to ascertain whether the effects are due to idio-retinal light and suggestion, some experiments were carried out in which suggestion was eliminated to the fullest extent.

In these tests the transformer was placed near the coil, so that the hum of the coil was completely drowned by the noise of the transformer. Arrangements were made whereby the current could be switched from the coil on to a resistance, the strength being maintained constant.

The subject's ears were plugged up, and a telephone receiver connected to the transformer was hung on the coil.

Under these conditions it was absolutely impossible to tell by the sound whether the current was on or off the coil; each of the observers was able, however, to identify the flicker with absolute precision when the current was switched on to the coil.

With a field alternating at a lower (twenty-five cycles per second) frequency, it was found that sensation was much more pronounced and intensely disagreeable, the whole visual field quivering as if illuminated by a rapidly intermittent light.

The effect was at all times very intense when the side of the head was presented to the coil, but on looking into the coil it practically disappears. From this Mr. Dunlap infers that the sensation is due to currents induced in the optic pathway; he states that whether these currents excite the occipital cortex directly, or excite the retina primarily, is a matter for conjecture; the fact that the flicker is produced by alterations faster than the fastest flicker from normal light stimulation being, it is stated, no evidence for the non-retinal character of the flicker in question.

It is stated that there was no evidence to show that

there was a definite arousal of visual sensation by the alternating field; the effect appeared more like an alternate intensification and inhibition of whatever sensory process was already in progress. That is to say, the idio-retinal light which is present before the current is turned on is increased and decreased alternately.

A KINETIC THEORY OF GRAVITATION.[1]

EVER since Sir Isaac Newton enunciated the law of universal gravitation, more than two hundred years ago, philosophers have speculated on the nature of that mysterious agency which links every atom of matter in the universe with every other atom. Newton found himself unable to offer any adequate explanation.

Since Newton's time several theories of gravitation have been proposed; but all, of which I am aware, are open to strong objections, and are not considered even promising by physicists.

Study of the nature of gravitation is beset with unusual difficulties, because gravitation is ever with us and about us; it is the one universal phenomenon, and we cannot escape from its influence—cannot obtain any outside point of view.

Gravitation is often described as a feeble force; and so it is, from one point of view. It is difficult to measure, or even to detect, attraction between two small bodies. But when the bodies are of planetary size the aggregate attraction of their molecules is enormous. It is easy to calculate that the attraction between the earth and the moon, which is just sufficient to retain the latter in its orbit, would, if replaced by a steel cable, require that the cable be about five hundred miles in diameter in order to withstand the strain. Between the earth and sun, the cable would have to be nearly as large in diameter as the earth; and attraction between the components of some double stars is millions of times greater than between the earth and sun (Lodge). So tremendous a phenomenon as gravitation, a phenomenon compared with which all others seem trivial, must have a mighty origin.

That gravitation is a phenomenon of the all-pervading æther is beyond reasonable doubt. This is so generally conceded that it need not be argued. But how does the gravitative influence originate? How is it transmitted and maintained? What is the *mechanism* of gravitation? It is the purpose of this paper to attempt an answer to these questions.

Let us consider what happens to a falling body. We know that it gathers kinetic energy from some source, as evidenced by its acceleration; that this energy may do external work or develop heat; that the amount of energy gathered is measured directly by the distance fallen through (within the limits of uniform gravitation), irrespective of the time or rate of falling. When the distance fallen through is of inter-planetary magnitude, and the attracting body large, the gathered energy is enormous, sufficient, if converted into heat, to vapourise the most refractory falling body.

We are here confronted with the question, Whence comes the energy acquired by a falling body? Certainly it was not inherent in the body before the fall, as evidenced by the fact that during unimpeded fall none of the physical or chemical attributes of the body, aside from the acquired motion, changes in the slightest degree.

We have been taught that before the fall the body was endowed with "potential energy of position," which is converted into kinetic energy during the fall. I think "energy of position" is an unfortunate term, because it is so very inadequate. To me it explains nothing. The case is not like that of a flexed spring, where there is internal molecular strain or displacement.

Let us imagine a pound-weight of iron, for instance, raised from the surface of the earth to a point near the moon in a line joining the centres of the two bodies, the point so chosen that the opposing attraction of the earth and the moon shall exactly balance each other, leaving orbital motion out of consideration.

On the surface of the earth the pound-weight had some so-called "potential energy of position," because it was capable of falling into a pit; but in its new position near the moon, this potential energy not only has not been augmented, but has disappeared entirely; the pound-weight, left free to move, remains stationary; and yet we must have expended more than twenty million foot-pounds of energy in overcoming the attraction of the earth and lifting the weight to its new position. This amount of energy would be sufficient to impart to the weight a velocity more than ten times greater than that of the swiftest cannon-ball, or, if converted into heat, would be many times more than sufficient to raise the iron weight to dazzling incandescence and then vapourise it. Now, in lifting the weight, this large amount of energy has disappeared utterly. We cannot believe that the whole or any part of it has been annihilated; it must, in some form, be resident somewhere. I think no one will contend that this energy is resident, in any form, in the cold, motionless pound-weight. I believe it was absorbed by, and is now resident in, the æther through which the weight was raised. Conversely, if this be true, a falling body must acquire its energy from the æther through which it falls. This is a fundamental idea to which I invite attention. Faraday glimpsed it long ago, and others have appreciated it more clearly since his time. But, so far as I am aware, no one has realised its significance.

This view of gravitation implies that the æther is endowed with very great intrinsic energy in some form. Many men of science now hold that the æther is so endowed, and that the amount of this intrinsic energy is enormous. Sir Oliver Lodge ("The Ether of Space") appears to regard this energy as potential in form, and estimates the intrinsic energy of a single cubic millimetre of the æther to be almost inconceivably vast. He says, "All potential energy exists in the ether." Sir J. J. Thomson says, "All kinetic energy is kinetic energy of the ether."

I conceive the æthereal energy involved in gravitation to be kinetic rather than potential, the latter involving strain or stress. Newton, and later Maxwell, assumed that bodies produce a stress in the æther about them of such nature as to account for gravitation, but they were unable to imagine any physical cause for the stress.

All the past theories of gravitation of which I am aware, except the corpuscular theory of La Sage, appear to regard gravitating matter as the seat of the gravitative influence, the surrounding æther, by induced stress or otherwise, acting simply as the medium of transmission. I cannot see that any of these theories accounts for the energy acquired by a falling body.

My own view of gravitation differs from these radically. I believe that kinetic energy of the æther is the fundamental cause of gravitation, and that a gravitating body plays a secondary *rôle* only in disturbing the normally uniform distribution of the æther's energy, in a manner I shall endeavour to explain later.

Let us assume, then, that the æther is endowed with very great kinetic energy normally uniform in distribution.

Kinetic energy implies motion of something possessed of inertia. Now, inertia is a fundamental attribute of the æther. Sir J. J. Thomson holds that all inertia is inertia of the æther. The æther is highly elastic also, which, with its inertia, enables it to possess kinetic energy in wave form, as exemplified in radiation. By the term wave, I mean progressive motion locally periodic; doubtless the æther as a whole is stationary. Hence we may consider the kinetic energy of the æther as consisting in æther waves of some kind.

These waves, vast in aggregate energy, eternal in persistence, without finite source or destination, are imagined as being propagated in straight lines in every conceivable direction. This isotropic distribution of kinetic energy, essential to my theory of gravitation, was, for me, a difficult conception until I reflected that isotropic radiant energy is approximately realised in the interior of any furnace with uniformly heated walls.

Any kind of waves capable of exerting motive action on the atoms or molecules of matter will fulfil the requirements; but I shall first consider the transverse, electromagnetic waves of radiation, because these are the kind of æther waves we are familiar with.

Of course, intrinsic æther waves, if of the radiation kind, cannot be of any frequency at present known to us as radiation, because then all bodies would become heated.

[1] Paper read before the American Association for the Advancement of Science, December, 1910, by Mr. Charles F. Brush.

But we can easily imagine them of such extremely low frequency that the molecules or atoms of matter cannot respond to them—cannot vibrate in unison with them—molecular resonance cannot be established; hence no conversion of the æther's energy *directly* into heat in the ordinary way can take place.

We are familiar with the dissipation or degeneration of the higher forms of energy into heat, and the continual degradation of heat to lower degree; that is to say, less violent molecular vibration and more general distribution. As is well known, it is only through this degradation or running down of natural energy that we are enabled to utilise some of it. Lord Kelvin called this function of energy "motivity" (we now call it entropy), and said the motivity of the universe tends to zero.

We know that ordinary radiation waves in the æther persist indefinitely and without change of frequency or direction until they encounter matter, when they are absorbed and converted into heat, only to be radiated again, usually in longer waves, to some colder body. This degradation of wave frequency continues until we can no longer follow it. I beg to suggest that the ultimate destination of this wave energy is that vast reservoir of kinetic energy intrinsic to the æther. We may liken the waves of radiant energy, which we apprehend as light and heat, to wind ripples on the surface of water, which continually degenerate in wave frequency until they are absorbed into and become a part of the mighty swell of the ocean.

Thus we may, perhaps, regard the æther's intrinsic energy as energy in its lowest form—Kelvin's zero of "motivity." But fortunately we may, and do, get some of this energy back in available form in several ways, as, for instance, when a falling body is arrested and develops heat; some of our wind ripples are then returned to us.

When two gigantic astronomical bodies collide under the influence of gravitation, as sometimes happens, we witness in far distant space the birth of a nebula. The inconceivably vast amount of heat developed by the collision converts both bodies into luminous vapour, which expands with incredible rapidity into the nebulous cloud. This heat energy must in course of time degenerate back into the æther whence it came, though billions of years may be required; and during all this time the energy has "motivity." We may picture the stupendous result of the collision as only a local splash in the æther's mighty ocean of energy.

Having postulated that the æther is endowed with very great intrinsic kinetic energy in wave form of some kind, that the waves are propagated in straight lines in every conceivable direction, *i.e.* the wave energy is isotropic, and that this energy is distributed uniformly throughout the universe except in so far as the distribution is disturbed by the presence of matter, I shall endeavour to explain my conception of the mechanism of gravitation.

For illustration in terms of the known, let us imagine a closed space having uniformly luminous walls of such character that every point on their surface radiates light in all internal directions. The enclosed space may be of any shape, but for the sake of simplicity let it be spherical or cubical, and large, say as large as a lecture-room. The space will be filled with isotropic radiant energy uniformly distributed—any cubic centimetre of space containing as much energy as any other.

Next let us picture a small opaque body suspended anywhere in our luminous space. The body may be of any shape we may imagine an atom or molecule to have; but, again for simplicity, let it be spherical—say a small grain of shot, and let it be located near the centre of the space.

The small body will absorb the light which falls upon it, and will cast a spherical shadow, the depth or intensity of which will vary inversely with the square of the distance from the centre of the body; and the shadow will extend to the confines of the enclosure, however large the latter may be. We cannot perceive the shadow, but we know it is there. It is true that the body will soon acquire the temperature of its surroundings, and radiate as much energy as it receives; but for the purpose of this illustration let us consider only the high-frequency light energy.

As is well known, the æther waves of light will exert a slight pressure on the body. But in the case supposed the pressure will be equal on all sides, and no effort toward translation can result.

Now let us introduce a second small body, similar to the first, and some distance from it. This also will cast a spherical shadow like the first. The two shadows will intersect, and each body will lie within the shadow of the other. In other words, each body will be partially shielded by the other from the æther waves coming from that direction. Hence the light pressure will be less on that side of each body which faces toward the other than on the side which is turned away, and the bodies will be urged toward each other by the excess of light pressure on the side turned away. This excess of pressure will vary with the inverse square of the distance between the centres of the bodies so long as the ratio of distance to diameters remains large.

The æther waves concerned in gravitation cannot, however, be like the light waves I have just used for illustration, because light waves heat bodies on which they fall; and their pressure is almost wholly superficial, it does not reach molecules much below the surface, and hence bears little relation to mass.

But let us substitute for the short and feeble waves of light powerful waves, still of the radiant kind, but of such great length and slow frequency that, as before explained, they do not excite the molecular vibrations which we appreciate as heat, and hence are not absorbed by matter; they pass freely through all bodies, bathing the interior molecules as effectually as those on the surface.

Under these conditions each molecule or atom or unit of a gravitating body will have its own spherical shadow or field of influence, and the gravitative force acting on the body will vary directly with the sum of its units, *i.e.* with its mass.

The spherical shadow which I have pictured as the field of influence of each atom or material unit implies that the atom has caused, principally in its immediate neighbourhood, a diminution of the æther's energy. Let us further imagine this subtracted energy resident in the atom as kinetic energy of translation in many paths, almost infinitesimally short and in every direction, but without collisions, because neighbouring atoms follow *very* nearly parallel paths. We may then picture the collective atoms or molecules of matter buffeted about in every direction by the æther waves in which they are entangled, like a suspended precipitate in turbulent water.

Each atom or molecule may be regarded as a centre of activity due to its kinetic energy of translation, with continual absorption and restitution of the æther's energy, normally equal in amount. The manner in which this molecular activity maintains, in effect, the supposed spherical shadow, requires explanation, which I shall attempt in a future paper.

Of the several components into which the composite motion of each atom can be resolved, that one lying in the direction of an attracting body will be the greatest, because the waves from that direction, being partially intercepted by the attracting body, are weakest, and the atom will be *pushed* in that direction by the superior waves behind it. If free to fall, the atom will continually absorb more energy from the stronger waves behind it than it restores to the weaker waves in front, and will thus acquire additional kinetic energy of translation in the line of fall, measured directly by the number of waves involved, *i.e.* by the distance moved. Conversely, if the atom be forced away from the attracting body, restitution of energy will exceed absorption, and the energy expended in moving the atom against attraction will be transferred to the æther.

It will be seen that gravitation is a *push* toward the attracting body, and not a pull. It is clear, also, that the velocity which a falling body can acquire tends asymptotically to a limit, which is the velocity of the æther waves which push it—the velocity of light, if transverse waves are involved.

I have already intimated that any kind of æther waves capable of imparting motion (not internal vibration) to the atoms of matter will fulfil the requirements of my theory, but have thus far discussed only transverse waves.

Let us now consider longitudinal waves—waves of compression and rarefaction, like sound waves in air and in

elastic liquids and solids. The "spherical shadow" conception which I have employed in connection with transverse waves applies equally well here.

So far as I am aware, longitudinal waves in the æther are unknown, but that such waves have not been observed is not convincing argument that they do not exist.

Assuming, then, that some, or perhaps much, of the intrinsic energy of the æther is embodied in longitudinal waves, we have only to find some motive action of such waves on atoms of matter to account for gravitation. Adequate motive connection may perhaps be effected by the locally alternating flow and ebb—acceleration and retardation of the æther in which the atoms are enmeshed, incident to its wave motion. We have ample reason for believing that the æther does obtain a grip of some sort on the atoms of an accelerating (falling) body and a retarding (rising) body, from which it follows that accelerating and retarding æther, as in a wave of compression, must grip a comparatively stationary atom.

Certain facts of astronomy apparently require that gravitational attraction between bodies, however distant from each other, must, in effect, be instantaneous; that is to say, the line of apparent attraction between them is a straight line joining their centres. I believe my theory meets this condition, but shall reserve discussion of the point for a future paper.

I feel much diffidence in presenting the foregoing rough draft of a theory of gravitation, but I cannot avoid the belief that it contains some germs of truth, perhaps the real key to the great mystery, though, if this be true, I have no doubt used the key clumsily and imperfectly.

If the æther-wave theory of gravitation is, in the main, the true one, it offers some hope of experimental verification. Provided the waves are of one principal frequency, or even of several, we may find something, doubtless of molecular magnitude only, which will oscillate in unison with them so that resonance can occasionally be established and a cumulative effect be obtained sufficient to manifest itself as heat.

In searching for some natural phenomenon of this nature, I thought of the thermal condition of the upper atmosphere as a possible case. The mean molecular velocity of a gas at some temperature, in connection with the mean free path of its molecules at some particular pressure or pressures, may possibly afford the necessary conditions for fortuitous resonance, with development of some slight amount of heat by the increased violence of inter-molecular collisions. I have done much experimental work on these lines during the past year, but, notwithstanding refinement of method and manipulation, the results have thus far been unsatisfactory. The work is still in progress, however, and investigation of other phenomena is contemplated.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—Mr. R. C. B. Gardner has been appointed assistant to the superintendent of the Museum of Zoology, and the appointment has received the consent of the Vice-Chancellor.

The special board for biology and geology has nominated Mr. J. F. Gaskell to use the University table at Naples for three months, and Mr. W. O. R. King to occupy the University table at the laboratory of the Marine Biological Association at Plymouth.

On Thursday, April 27, a Grace will be brought before the Senate suggesting that the laboratory of experimental psychology syndicate be authorised to obtain tenders for the erection of a building for the psychological laboratory in accordance with Mr. Jackson's plans, and that the Vice-Chancellor be authorised to sign the contract for the work provided that the total cost does not exceed 4250*l.*

IT is announced in the *Revue scientifique* that Mr. Arthur Krupp has given 50,000 crowns to the Vienna School of Arts and Crafts towards the establishment of an aviation laboratory.

IN connection with the celebration of the centenary of the University of Breslau, Dr. P. Schottlaender has given the University 450,000 marks, the interest of which, says the *Revue scientifique*, is to be devoted to the provision of travelling exhibitions or to the purposes of research.

AT a meeting of the London branch of the Association of Teachers in Technical Institutions, to be held on Saturday, March 25, at the South-Western Polytechnic, Chelsea, S.W., a conference on the organisation of technical instruction, especially in connection with the higher branches, will be opened by Dr. R. T. Glazebrook, F.R.S., director of the National Physical Laboratory.

THE London Inter-collegiate Scholarships Board announces that an examination will be held on May 9 for eighteen entrance scholarships and exhibitions, of an aggregate total value of about 1500*l.*, open to men and women, and tenable in the faculties of arts, science, and engineering of University College, King's College, and the East London College. Particulars and entry forms may be obtained from the secretary of the Board, Mr. A. E. G. Attoe, University College, Gower Street, W.C.

MR. ALEXANDER SIEMENS, president of the Institution of Civil Engineers, speaking at the annual dinner of the institution on March 17, said that the institution proposes to inaugurate a conference on engineering education during the summer with the object of making clear the proper way of preparing young men for the profession of engineering. The passing of examinations is part of what is needed, he pointed out, but not all. The great thing is practical training, so that young men may know how to employ their theoretical knowledge and be prepared to take up any branch of engineering which fate may drive them to. Mr. Siemens hopes that the institution will have an opportunity at the forthcoming Imperial Conference to represent to the Colonies the desirability of recognising the qualifications of its members and of according them uniform treatment throughout the Empire.

THE Home Secretary has appointed a committee to inquire into the constitution, management, discipline, and education of reformatory and industrial schools in England and Wales. The inquiry will include a consideration of the relation of the schools to education committees and other authorities, and the qualifications of superintendents and other officers; variation in the types of schools, and whether further provision is necessary for the proper grading of boys and girls; the suitability of ships for use as schools; the preparation given boys for entry into industrial or other careers, and the training and disposal of girls; the care of boys and girls after leaving the schools and the relation of the schools in this connection to existing institutions for the welfare of young persons. The committee appointed is representative in character, and Mr. C. F. G. Masterman, M.P., is the chairman. Mr. A. Maxwell, of the Home Office, will act as secretary.

THE Board of Education has found it impossible to complete the preparation of the new grant regulations for technical schools, schools of art, and other forms of provision of further education in England and Wales, at as early a date as was suggested in the prefatory memorandum to the regulations issued last August. This being so, the Board feels that to bring new regulations into force by August 1 next would allow insufficient time to education authorities for accommodating their arrangements to the requirements of the new regulations. The grant regulations for 1910 are, therefore, to be continued in force during the educational year 1911–12, and the Board hopes in the course of the coming summer to issue the new regulations, which will not, however, become operative until the educational year 1912–13. The new regulations may thus be in the hands of education authorities a year before they come into force. The Board announces, however, that it will not be necessary similarly to defer the issue or the operation of the new regulations for university institutions. The Board contemplates issuing separate provisions in respect of the educational year 1911–12 for the payment of grant in aid of approved courses provided by university institutions. Any courses so aided will cease to be eligible for recognition under the Board's regulations for technical schools. New regulations for the science and art examinations, the National competition, and the various forms of scholarships and exhibitions given and aided by the Board are under consideration, and it is hoped that

some of the changes involved may be announced in the course of this summer, and may become operative in the summer of 1912.

IN the issue of *Science* for March 3, Prof. Rudolf Tombo, jun., analyses the registration returns for November 1, 1910, of twenty-seven of the leading universities in the United States. Four of the universities show a decrease in their total enrolment of students, viz. Harvard, Iowa, Indiana, and Virginia, as against four in 1909, two in 1908, and five in 1907. If the returns of the number of students for 1910 be compared with those of 1909, we note that Chicago and Michigan have passed Harvard, that Pennsylvania has changed places with Cornell, that Illinois has been passed by Minnesota, California, and Wisconsin, that North-western has passed Yale, and that Johns Hopkins and Virginia have changed places. For the first time in the annals of American universities the 7000 mark has been passed, Columbia having a grand total of 7411 students. Pennsylvania is the sixth university in the States to pass the 5000 mark; Cornell passed it in 1909, Chicago and Michigan in 1908, Columbia in 1907, and Harvard somewhat earlier. The number of students of science in American universities is decidedly smaller than in 1909, and more than half these institutions showed a loss of students in these departments as compared with the previous year. The chief gains were made by Illinois, Yale, and Columbia in the order given. Cornell, Michigan, Illinois, and Yale each enrolled more than a thousand students of engineering. It is noteworthy that the number of undergraduate women students shows a decrease at the majority of the institutions. All the schools of agriculture continue to show an increase in the number of students, and that in connection with the University of Minnesota is still at the head of the list.

SIR ALFRED KEOGH, rector of the Imperial College of Science and Technology, distributed the prizes and certificates to the students of the South-Western Polytechnic Institute, Chelsea, on March 10. In the course of his address he pointed out the deplorable lack of system which exists in the methods of technological education in London. He advocated the creation of a central institution of university rank to which the other institutions might send their most promising students. He also suggested the formation of technological boards of studies composed of the various teachers of technology in London. The annual report of the institute stated that the progress of the work is satisfactory, particularly in the higher branches of science. During the last session twenty-four students attained the London B.Sc. degree, of whom fourteen graduated in honours. Two old evening students obtained the D.Sc. degree. In the Board of Education examinations fourteen obtained honours certificates. A considerable amount of research was completed during the year and contributed to various scientific societies and periodicals. Mr. Hayes Fisher, M.P., chairman of the governing body, alluded sympathetically to the recent loss sustained by the death of Mr. R. C. Antrobus, who for nearly twenty-five years was closely associated with the work of the institute, including ten years' service as chairman of the governing body. Mr. Fisher also stated that they would be shortly in a position to start upon the new buildings, which will furnish accommodation for natural science laboratories and class-rooms, a new physical laboratory, and new and efficient social rooms. After the meeting, the laboratories, workshops, and other rooms were thrown open for inspection. About 1500 visitors availed themselves of this opportunity to inspect the buildings and apparatus.

REPLYING to a deputation from the Trade Union Congress Parliamentary Committee on March 16, Mr. Runciman, President of the Board of Education, dealt with the question of "half-time" pupils in elementary schools. He said the Board of Education has been at work for some time on schemes for linking up continuation classes, and compulsory attendance at continuation classes, with other educational reforms. The Departmental Committee which inquired into the question of "half time" came to the conclusion that the time had arrived for the raising of the half-time age. A Bill will be introduced very shortly into the House of Commons to carry out some of the recommendations of that committee. Continuation-class work ought not, he said, to end at the age of fourteen, but be carried through that period of adolescence in which the boy has lost his habit of learning and has not acquired the proper taste of learning. The Board wishes to keep alive what are called "humanities" as well as technicalities. In trade schools the Board already gives assistance, and it is revising its educational regulation to assist the schools still further. The deputation asked for an inquiry into the question of endowments, but Mr. Runciman, though he has the subject under consideration, said he was unable to promise the appointment of a Royal Commission on the subject. According to *The Times*, the Bill which Mr. Runciman will introduce to deal with half-time attendance will follow the recommendations made by the Inter-Departmental Committee on Partial Exemption from School Attendance, which reported in August, 1909. In reporting against the continuance of the system, the committee recommended that total exemption under the age of thirteen be abolished; that the attendance certificate for total exemption be abolished; that total exemption at the age of thirteen be granted only for the purposes of beneficial or necessary employment; that the ordinary condition for total exemption be due attendance at a continuation class, but that, subject to the approval of the Board of Education, an authority may adopt as an alternative condition the passing of a standard not lower than Standard VI. The committee anticipated that the abolition of partial exemption, coupled with the raising of the minimum age for exemption to thirteen, would necessitate provision being made in the day schools for the instruction of about 22,550 additional whole-time scholars, and would result in an increased cost to the Exchequer to the amount of 22,540*l*.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, March 16.—Sir Archibald Geikie, K.C.B., president, in the chair.—L. **Doncaster**: Gametogenesis of the gall-fly (*Neuroterus lenticularis*). Part ii. This paper is a continuation of the paper on the same subject published in the Proc. Roy. Soc., B, vol. lxxxii., 1910, p. 88. The previous part dealt with the spermatogenesis and maturation of the eggs of the summer (bisexual) generation. The present part describes the maturation of the eggs in the spring (parthenogenetic) generation. It is found that there are two types of eggs, laid by different females. In one there is a double polar division, by which the somatic number of chromosomes (20) is reduced to 10, and, since the eggs are unfertilised, 10 chromosomes appear in the segmentation divisions. In eggs laid by other females no maturation division occurs; the egg nucleus, after moving to the edge of the egg as if preparing for maturation, sinks in again, and immediately undergoes the first segmentation division. In eggs of this type 20 chromosomes are found in the segmentation spindles, and polar nuclei are absent. Since experiment shows that some females lay only male-producing eggs, others only female-producing, and since male larvæ show the reduced chromosome number (10) in the germ-cells and nervous system, while female larvæ have 20, it is concluded that the parthenogenetic eggs which undergo reduction yield males, those which do not, females.—Sir Thomas R. **Fraser** and Dr. J. A. **Gunn**: The action of the venom of *Echis carinatus*. The minimum lethal dose of Echis venom by subcutaneous injection per kilogram was found to be:—for the frog, 0·009 gram; for the rabbit, 0·0009 gram; for the rat, 0·00075 gram; for the cat, 0·008 gram; and for the pigeon, 0·004 gram. The frog and the cat, therefore, show a relatively high resistance to this venom, the minimum lethal dose for these animals being about ten times that for the rabbit or rat. In the case of Sepedon venom, which may be taken as a typical Colubrine venom, a different ratio of lethality has been found by us for those animals, the cat showing a relatively even higher resistance, but the frog no increased resistance, as compared with the rabbit or rat. This of itself points to an intrinsic difference between the actions of Viperine and Colubrine venoms. The chief effects produced by Echis venom in the animals investigated are hæmorrhages occurring

locally and distally, alterations in the coagulability of the blood, and secondary effects upon the respiration, heart, and central nervous system. The symptoms of experimental poisoning thus very closely resemble those which have been described in cases of Echis bite in man. Echis venom differs from Colubrine venoms in having little or no direct action on the central nervous system or on the nerve terminals in voluntary muscle. It has a direct action in lowering the blood-pressure in mammals by slowing and weakening the heart's contractions; lethal doses also produce a fall of temperature in mammals. The chief toxins in Echis venom, in the order of their potency, are a hæmorrhagin, a substance which alters the coagulability of the blood, and a hæmolysin.—Sir David **Bruce**, Captains A. E. **Hamerton** and H. R. **Bateman**, and Captain F. P. **Mackie** (Sleeping Sickness Commission of the Royal Society, Uganda, 1908–10). Further researches on the development of *Trypanosoma gambiense* in *Glossina palpalis*. (1) In the course of the development of *Trypanosoma gambiense* in *Glossina palpalis*, the proboscis does not become involved, as in the case of some other species. (2) A few days after an infective feed the trypanosomes disappear out of the great majority of the flies, but in a small percentage this initial disappearance is followed by a renewed development. (3) After a very short time the flies which have fed on an infected animal become incapable of conveying the infection by their bites, and this non-infectivity lasts for some twenty-eight days, when a renewed or late infectivity takes place. (4) A fly in which this renewed or late infectivity occurs can remain infective for at least ninety-six days. (5) An invasion of the salivary glands occurs at the same time as this renewal of infectivity, and without this invasion of the salivary glands there can be no infectivity. (6) The type of trypanosome found in the salivary glands when the fly becomes infective is similar to the short, stumpy form found in vertebrate blood, and it is believed that this reversion to the blood type is a *sine qua non* in the infective process.—Dr. M. **Haaland**: Spontaneous cancer in mice. The observations recorded have been made upon 300 mice in which cancer had developed spontaneously. The tumours originally observed numbered 350. Many of the mice presented multiple growths. It is important that forty-two tumours had a structure distinct from that of the well-known mammary tumours of the mouse. Spontaneous healing is recorded of undoubted malignant new growths. The reasons have been sought for that preponderance of mammary tumours which is characteristic for the mouse. The physiological demands made upon the mamma by repeated pregnancy and lactation can be excluded, since many of the mice which had been under observation since birth had never littered, and twenty had been completely isolated from possibility of association with a male. The histological examination of the mamma of a large number of old mice, cancerous and non-cancerous, showed the frequency of chronic inflammation combined with hypertrophic and other changes in the epithelium. The latter pass through all stages to definite tumours. The only explanation found for the chronic inflammatory and other changes was the presence of nematodes. Numerous experiments of diverse kind were made to define the parts played by local causes, such as those described above, and by constitutional conditions. All the evidence points to the importance of local causes, *e.g.* chronic irritation, and to the absence of general constitutional changes favourable for the growth of cancer. The part played by the irritant is a mediate one, so that it produces the altered conditions under which either the first departure of the cells from the normal takes place, or permits spontaneously occurring sports of cells to multiply and adapt themselves to a new mode of life as observed in propagated tumours.

Geological Society, March 8.—Prof. W. W. Watts, president, in the chair.—Contributions to the geology of Cyrenaica, by Prof. J. W. Gregory and others. (1) Prof. J. W. **Gregory**: The geology of Cyrenaica. According to the evidence available in 1908 regarding Cyrenaica, the country might be interpreted as a fragment of a mountain-loop, or as a plateau of Miocene rocks. In a journey across the country, the author found that it was a plateau of Lower Kainozoic limestones. These limestones must have been deposited in a clear sea, at depths down to 1000 fathoms. Intervals of shallow sea a[re] indicated by limestone-conglomerates and coral-reef lim[e]stone. The country was uplifted in later Miocene tim[es] and was then part of a wide land which included Cre[te] and occupied the site of the Ægean Sea. This land w[as] broken up by great subsidences, which left Cyrenaica [as] a horst bounded by fault-scarps on the north and we[st]. Cyrenaica may be regarded as part of the western limb [of] the geosyncline of western Egypt.—(2) R. B. **Newton**: Notes on the Kainozoic Mollusca. A number of Mollus[ca] are recognised as belonging to members of the Kainozo[ic] system. The most abundant of the post-Pliocene series [is] *Cerastoderma edule*. Among the Helvetian-Tortonia[n] forms are *Alectryonia* cf. *virleti* and *Strombus* cf. *cor[o]natus*. The Aquitanian shells present a relationship to t[he] "Schioschichten" fauna of northern Italy. Foraminifer[al] organisms occur in these beds, but no nummulit[es]; *Lepidocyclina elephantina*, a good Aquitanian species, [is] found with *Oopecten rotundatus* from Birlibah. The mo[st] characteristic of the Priabonian Mollusca is *Pect[en] arcuatus*. A new species of Æquipecten is describe[d]. Nummulites abound in these rocks. So far as the Mo[l]lusca are concerned, nothing older than Lutetian has be[en] observed.—(3) F. **Chapman**: Foraminifera, Ostracod[a], and parasitic fungi from the Kainozoic limestones [of] Cyrenaica. The Foraminifera are mainly from the Midd[le] Eocene; others belong to the Upper Eocene and to t[he] Aquitanian or Stampian. The most abundant foraminif[er] is *Nummulites gizehensis*. At a higher horizon is [a] nummulitic limestone containing *N. gizehensis*, var. *lyel[li]*. Some limestones at Wadi Umzigga contain *Lepidocycli[na] elephantina*, and are referred to the Aquitanian [or] Stampian. The boring fungus *Palaechyla perforans* occu[rs] perforating Lepidocyclina.—(4) Prof. J. W. **Gregory**: The fossil Echinoidea of Cyrenaica. The Echinoidea a[re] referred to ten species, of which two are new, and one [is] a new variety. The echinoids come from four horizon[s]; the oldest fauna belongs to the Middle Eocene; the Upp[er] Eocene is represented by an unusually early species [of] Amphiope, and by an Echinolampas. Some echinoi[ds] from the Cyrene limestones are of Aquitanian affinitie[s], and others seen in the limestone east of Benghazi a[re] Miocene. The echinoid faunas show that the Eoce[ne] rocks containing them were, as a whole, deposited in [a] sea of moderate depth.—(5) D. P. **MacDonald**: T[he] foraminiferal limestones of Cyrenaica. The microscop[ic] examination of the limestones shows that they are main[ly] composed of organic material, and are free from detrit[al] material. Some of them have been partly dolomitise[d]. Some of the limestones are oolitic.—G. E. **Dibley**: T[he] teeth of the genus Ptychodus, and their distribution in t[he] English Chalk. This paper is an attempt to define t[he] species of the fossil fish genus Ptychodus. Hitherto, o[ur] information as regards Ptychodus has been derived fro[m] associated sets of *P. decurrens* in place and isolated tee[th] of this and other species. The variation in teeth of o[ne] individual is often so marked that, when found separatel[y], they have given rise to the formation of new species. [It] can now be proved that these teeth belong to alrea[dy] known species, and merely represent a phase in variatio[n] in the development of certain teeth of one species. Speci[al] attention has been given to the extreme variation [in] *P. decurrens*, as well as in the equally variable speci[es] *P. polygyrus*, and one new species has been added.

Zoological Society, March 7.—Dr. A. Smith-Woodward, F.R.S., vice-president, in the chair.—Dr. Karl **Jorda[n]** and the Hon. N. Charles **Rothschild**: Some Siphonapter[a] from northern China. This collection of fleas had bee[n] made by Mr. M. P. Anderson, the Duke of Bedford['s] collector, in the province of Shen-si, and containe[d] altogether seventeen species, of which no fewer tha[n] thirteen were new. Some of these were possibly on[ly] geographical developments, but others represented distin[ct] types not very nearly allied to any known species.—F. [E.] **Beddard**: Certain points in the anatomy of the fro[g] *Megalophrys* (*Leptobrachium*) *feae*, based on specimen[s] exhibited in the society's gardens.—F. E. **Beddard**: The spermatophores in earthworms of the genus Pheretim[a] (=Perichæta). These structures had been found in tw[o] species, one of which would be described as new, co[n]tained in a collection of terrestrial Oligochæta from th[e]

Philippine Islands, which had been submitted to him for examination by the director of the Scientific Bureau of the Philippines.—R. **Lydekker**: (1) A rare beaked whale; (2) age phases of the rorqual.—Dr. P. Chalmers **Mitchell**: Longevity and relative viability in mammals and birds, with a note on the theory of longevity. The work was based on a study of the records of the duration of life in the society's gardens of more than 20,000 individual mammals and birds. These were arranged systematically so as to make possible a comparison of the average duration with the maximum duration and what was known or could be inferred as to the potential longevity. Such a method gave a measure of the effect of the conditions of captivity on the duration of life. The memoir discussed some of the results obtained by such a comparison, particularly with regard to the provision of artificial heat. In the note on the theory of longevity, the author briefly reviewed the contributions of Ray Lankester, Weismann, and Metchnikoff, and stated his conclusion that potential longevity was due to constitutional causes, that the constitution was adapted to the average specific longevity, and that the correlation between longevity and reproduction was the reverse of what had been suggested by Weismann.

DUBLIN.

Royal Dublin Society, February 28.—Prof. T. Johnson in the chair.—W. J. **Lyons**: The determination of density, thermal expansion, and volume-change on fusion of waxes. The author described a simple but effective apparatus for the exact determination of the density of liquid and solid fats and waxes at any temperature. The method can be applied to examine the continuous change in volume on change of temperature, and the abnormal volume change on fusion. Some interesting results were shown for beeswax and other waxes.—R. J. **Moss**: A simple form of apparatus for drying substances *in vacuo* at the temperature of boiling water. Finely powdered selenite lost 93·4 per cent. of the total water of crystallisation in one hour by this method, whereas when dried for five hours in the water oven in the ordinary way the loss was only 72·7 per cent.

PARIS.

Academy of Sciences, March 13.—M. Armand Gautier in the chair.—H. **Le Chatelier**: The alterability of aluminium. After some months' use, a marked alteration in the surface of some aluminium utensils was noticed. Photomicrographs are reproduced in the paper showing the nature of the change. The metal developed a crystalline structure, and the crystals tended to become isolated from each other. Some laboratory experiments made with a view to imitate this cellular structure, and to obtain a separation of the grains, have shown that aluminium containing small quantities of calcium lends itself more easily to the reproduction of this structure.—Gaston **Bonnier**, Louis **Matruchot**, and Raoul **Combes**: Researches on the determination of microscopic germs in the atmosphere. Previous researches on this subject have been chiefly directed to the determination of bacteria, and very few have considered the question of the fungi. The apparatus used in this work is described in detail, and a preliminary account of the results is given. The work includes the influence of the culture medium on the development of the organisms, the influence of the surrounding vegetation on the dissemination of the germs, and the influence of the altitude. Amongst other results, the presence of numerous colonies of moulds has been proved in a sample of snow taken on the Pic du Midi at an altitude of 2860 metres. As regards the effect of altitude, the fact already known that the proportion of bacteria diminishes rapidly with the altitude has been confirmed, but, so far as the moulds are concerned, this diminution is less marked, as even at high altitudes numerous mould spores are still found.—A. **Chauveau**: The battle of the visual fields in the stereoscope. A continuation of the work described in an earlier communication (February 27). The results are summarised in ten conclusions, too lengthy for reproduction.—Pierre **Termier**: The age of the green rocks of the Belledonne chain. The green rocks at Tabor are not metamorphosed from the Lias nor from the Trias, and are, indeed, much earlier than the latter.—Paul **Sabatier** and A. **Mailhe**: The catalytic splitting up of esters by certain metallic oxides. Esters may split up catalytically in several directions, forming ketone and carbon dioxide; ethylenic hydrocarbon and water; ketone, carbon dioxide, hydrocarbon and alcohol; acid and hydrocarbon. Examples are given of all these cases, and it is shown that the nature of the acid, the temperature, and the nature of the metallic oxide all have an influence on the course of the reaction.—M. Pavlov was elected a correspondant in the section of medicine and surgery in the place of the late M. Herrgott, and S. Arrhenius a correspondant in the section of physics in the place of the late M. Hittorf.—M. **Nicolau**: The variation in the motion of the moon.—Zoárd **de Geöcze**: Contribution to the quadrature of curved surfaces.—Henri **Villat**: The problem of Dirichlet relating to a circular corona.—Gustave **Dumas**: The resolution of the singularities of surfaces.—C. **Tissot**: The exact determination of the periods of electrical oscillations. A discussion of the limitations of the method described in a previous paper.—C. **Gutton**: A comparison of the velocities of propagation of light and of electromagnetic waves along a wire. The comparison of the velocities of light and electromagnetic waves has hitherto been obtained by the determination of each magnitude separately. By utilising the electrical double refraction of carbon bisulphide, the author makes a direct comparison of the two velocities without measuring either separately. The two velocities were found to be equal within 1 per cent., or within the limits of accuracy of the experimental method employed.—Pierre **Weiss**: Magneton in solid paramagnetic bodies.—Ch. **Moureu** and A. **Lepape**: A spectrophotometric method for the estimation of krypton, especially of the yellow line 5871·12 and the green line 5570·50, and the regular increase in the intensity of the yellow line in a mixture of argon and krypton. This line is in the region of the spectrum in which the eye has a maximum sensitiveness. The results are based on the proportion of krypton in atmospheric argon as found by Sir William Ramsay, but experiments are in progress to make up standard mixtures of pure krypton in pure argon. The minimum amount of krypton that it has been found possible to estimate is about 0·001 cubic millimetre in 4 four cubic centimetres of the krypton-argon mixture.—A. **Lafay**: The utilisation of the acetylene method for the measurement of the velocity of the wind and the study of the aërodynamic field. Comparison of the velocities measured by the vane anemometer and the Pitot tube, respectively, frequently give very discordant results. The method proposed by the author is based on the high refractive index of acetylene. A jet of acetylene is cut off periodically at known intervals of time, and the regularly spaced nebulosities photographed. The results obtained agree better with the indications of the vane anemometer than with those of the Pitot tube.—M. **de Broglie**: The lowering of the differences of the contact potential apparent between metals caused by the removal of the adherent layers of moisture.—M. **Dussaud**: New applications of low voltage bulbs. Some applications of the intense light obtained by tungsten wires in a high vacuum carrying 1 ampere at 15 volts. This lamp, using only 15 watts, may replace for some purposes an arc using 3000 watts.—Maurice **Joly**: Static frequency transformers.—André **Kling**: The influence of catalytic substances in the determination of vapour density. Different results are obtained in a Victor Meyer vapour density tube according to the presence or absence of a layer of calcined sand at the bottom of the tube. The sand in some cases causes a catalytic decomposition of the substance vapourised, and the vapour density is thus found too low. The replacement of the sand by other metallic oxides known to possess catalytic properties has been studied.—M. **Hanriot**: The nature of adhesivity.—Jean **Meunier**: The modification of the mechanism of flame by convergent combustion.—Mlle. E. **Feytis**: The magnetism of some complex salts.—W. Œchsner **de Coninck**: An attempt at the determination of the molecular weight of uranyl. Five determinations are given of the reduction of uranyl chloride, UO_2Cl_2, in hydrogen at a dull heat, the residual UO_2 being weighed.—V. **Auger**: The oxidation of iodine by hydrogen peroxide. In dilute solution and in presence of a trace of chloride, iodine is quantitatively oxidised to iodic acid by hydrogen peroxide. The iodic acid is recovered in a pure state by simple evaporation.—A. G. **Vournasos**: Some definite bismuthides.—E.

Flourent and Lucien **Lévi**: A method for the exact determination of the ash in the analysis of vegetable and animal materials.—MM. **Taffanel** and **Durr**: The comparative study of combustible dusts from the point of view of their inflammability.—Const. A. **Ktenas**: An acid eruption at the centre of the *massif* of the Cyclades.—L. **Gain**: A new species of Monostroma coming from the South American Antarctic region.—MM. **Doyon**, A. **Morel**, and A. **Policard**: The direct extraction of hepatic antirhombine. The case of the rabbit refractory to the action of the peptone.—L. **Grimbert**: The separation of urobiline with its chromogen.—J. **Wolff** and E. **de Stœcklin**: A new mode of preparation of the catalase of the blood and on its properties.—W. **Nicati**: The capacity

$$VC = 0{\cdot}1(11 - V),$$

inverse decimal function of the visual angle.—J. P. **Bounhiol**: A hydrodynamic theory of the pseudo-migrations of the tunny fish (*Thynnus vulgaris*) in the Mediterranean.—J. **Deprat**: The classification of fusiline limestones in China.

GÖTTINGEN.

Royal Society of Sciences.—The *Nachrichten* (physico-mathematical section), part vi. for 1910, contains the following memoirs communicated to the society:—

May 2.—D. **Hilbert**: Outlines of a general theory of integral equations.

October 29.—O. **Wallach**: Researches from the Göttingen University chemical laboratory, xxiv.: (1) Reduction of unsaturated cyclic alcohols; (2) reduction of unsaturated ketones.

November 26.—W. **Voigt**: Changes in concentration of the solution of a magnetisable salt in a non-homogeneous magnetic field.

December 10.—P. **Furtwangler**: Researches on the last of Fermat's theorems and the division of the circle.—J. **Yoshikawa**: Boundary-value problems with three parameters.—J. **Yoshikawa**: A theorem in oscillations with two parameters.—E. **Hecke**: Real quadratic groups and automorphic functions.

DIARY OF SOCIETIES.

THURSDAY, MARCH 23.

ROYAL SOCIETY, at 4.30.—A Theory of Asymptotic Series: G. N. Watson.—The Ionization of Heavy Gases by X-rays: R. T. Beatty.—The Variation of the Ionization with Velocity for the β-Particles: W. Wilson.—The Causes of Absorption of Oxygen by the Lungs in Man: C. G. Douglas and Dr. J. S. Haldane, F.R.S.—The Influence of Planets on the Formation of Sun-spots: Dr. A. Schuster, F.R.S.

ROYAL INSTITUTION, at 3.—Giants and Pygmies: Prof. A. Keith.

INSTITUTION OF ELECTRICAL ENGINEERS, at 8.—Electricity Meters with Notes on Meter Testing: H. A. Ratcliff and A. E. Moore.

FRIDAY, MARCH 24.

ROYAL INSTITUTION, at 9.—The Sidereal Universe: Sir David Gill, K.C.B., F.R.S.

PHYSICAL SOCIETY, at 5.—(1) A Sensitive Thermo Regulator; (2) Experiments on the Measurement of Electrolytic Resistances using Alternating Currents: Dr. H. F. Haworth.—(1) Oscillatory Currents in Coupled Circuits; (2) Some Radio-telegraphic Apparatus in Use at the City and Guilds (Engineering) College: Prof. G. W. O. Howe.

INSTITUTION OF CIVIL ENGINEERS, at 8.—The Uses of Chemistry in Engineering: James Swinburne, F.R.S.

SATURDAY, MARCH 25.

ROYAL INSTITUTION, at 3.—Radiant Energy and Matter: Sir J. J. Thomson, F.R.S.

MONDAY, MARCH 27.

ROYAL GEOGRAPHICAL SOCIETY, at 8.30.—The New Geography: its Aims and Methods: H. J. Mackinder, M.P.

ROYAL SOCIETY OF ARTS, at 8.—Applications of Electric Heating: Prof. J. A. Fleming, F.R.S.

INSTITUTE OF ACTUARIES, at 5.—State Insurance against Invalidity and Old Age—the Actuarial Basis of the Austrian Method: G. W. Richmond.

TUESDAY, MARCH 28.

ROYAL INSTITUTION, at 3.—Explorations of Ancient Desert Sites in Central Asia: Dr. M. A. Stein.

INSTITUTION OF CIVIL ENGINEERS, at 8.—*Further discussion*: The Electrification of a Portion of the Suburban System of the London, Brighton and South Coast Railway: P. Dawson.—*Probable Papers*: The Improvement of Highways to meet Modern Conditions of Traffic: J. W. Smith.—Recent Development in Road-traffic, Road-construction and Maintenance: H. P. Maybury.

WEDNESDAY, MARCH 29.

ROYAL SOCIETY OF ARTS, at 8.—Art Education in Jewellery, Goldsmithing, and Allied Trades: G. B. Heming.

BRITISH ASTRONOMICAL ASSOCIATION, at 5.

THURSDAY, MARCH 30.

ROYAL SOCIETY, at 4.30.—*Probable Papers*: The Chemical Dynamics of Serum Reactions: Captain A. G. McKendrick.—Preliminary Note on a Method of Measuring Colour Sensations by Intermittent Light, with Description of an Unfinished Apparatus for the Purpose: Dr. G. J. Burch, F.R.S.—On Variation and Adaptation in Bacteria, illustrated by Observations upon Streptococci; with special reference to the Value of Fermentation Tests as applied to these Organisms: E. W. A. Walker.—On the Inter-relations of Genetic Factors: W. Bateson, F.R.S., and Prof. R. C. Punnett.—A Case of Gametic Coupling in Pisum: P. de Vilmorin and W. ENTOMOLOGICAL STUDIES AND PROBLEMS.

The Hope Reports. Vol. vii., 1908–10. Edited by Prof. Edward B. Poulton, F.R.S. (Oxford: Printed for private circulation by Horace Hart, 1910.)

THIS seventh volume of "Hope Reports" contains publications that have appeared between June, 1908, and June, 1910. It contains a mass of interesting material testifying to active interest taken in entomological studies and problems. The volume opens with an account of Dr. F. A. Dixey's patient and exhaustive investigation into the scent-distributing plume scales of the Pierine butterflies. These plume scales, when present, are found only in the male, and are confined to the upper surface of the wings, sometimes scattered over the general surface of both fore and hind wings, sometimes confined to special areas. An odoriferous secreted substance volatilises, and passing through the scales diffuses, giving an odour characteristic of the species of butterfly. Dr. Dixey passes in review many Pierine butterflies, and describes the structural characters and the various forms and distribution of the scent-scales, and suggests as a result of his research that the scent-scales have a diagnostic value for specific and certainly for generic distinctions. Further, the occurrence and the character of the scales can afford subsidiary evidence to other and more relied-on evidences of affinity.

The never-failing interest in the highly involved phenomenon of protective mimicry is a subject in which British workers—Oxford holding a deservedly foremost place—have won a world reputation, and this explains, and receives justification in, a series of memoirs in this volume of "Hope Reports." Prof. Poulton describes material from Durban, experimentally obtained by Mr. G. F. Leigh from the three mimetic female forms of *Papilio dardanus*, Brown, subspecies *cenea*, Stoll. In dealing with hereditary relationships of the several female forms, evidence is afforded that the proportion of mimetic forms in a locality is due partly to the proportion of, and partly to the relative conspicuousness of, their particular models, and the way is suggested in which the details of mimetic patterns have become adjusted to those of the models. A second paper, by Prof. Poulton, on the mimetic North American species of the genus Limenitis and their models, is followed by "Some Bionomic Notes on British East African Butterflies," by the Rev. K. St. Aubyn Rogers, who, in a long paper, illustrated by four plates, gives many original observations bearing on mimicry and its problems. J. C. Moulton follows with an illustrated account (five plates) of some of the principal mimetic (Müllerian) combinations of tropical American butterflies, and Dr. G. B. Longstaff, in a memoir full of observation, gives many bionomic notes on butterflies from different parts of the world.

In all the above memoirs there is much new information, and additional experimental and observational evidence in favour of Batesian and Müllerian mimicry.

The protective mimicry theory can only justify itself if there be proof that the mimics receive protection from insectivorous enemies, and in this connection attention may be directed to memoir No. 8 of these "Hope Reports," where Mr. Guy A. K. Marshall, in "Birds as a Factor in the Production of Mimetic Resemblance among Butterflies," deals with the debated question of appetite for butterflies among birds. Mr. Marshall gives here a very satisfying and most helpful review, in fifty-three pages, of such appetite and attack, summarising the evidence from world's records.

In memoir 9, "An Account of Some Experiments on the Edibility of Certain Lepidopterous Larvæ," Mr. Eltringham, in experiments where various larvæ were offered to lizards, obtained interesting results with caterpillars of *Boarmia rhomboidaria*. These caterpillars are well known to have a very marked resemblance to ivy twigs, and when motionless may easily be mistaken for twigs. One would have expected that this caterpillar, on being discovered, would prove palatable, whereas these *Boarmia rhomboidaria* caterpillars, fed on ivy, proved most distasteful to lizards. The same caterpillars, however, fed on apple for some days, were taken most willingly by the same lizards.

The systematic side of entomology is represented in the "Reports" by a series of memoirs on the Orthoptera. Three of these are on the Blattidæ by an expert in this family, viz. Mr. R. Shelford, who also writes on "Two Remarkable forms of Mantid Oothecæ." Dr. Hancock, of Chicago, describes Tetriginæ in the Oxford University Museum, and Dr. Achille Griffini, of Genoa, has three papers on the material at Oxford of Gryllacris, a genus of Locustidæ.

Mr. A. H. Hamm describes the courtship of some Empid species, supplementing previous observations by Howlett. The Empidæ, or dance-flies, are predaceous flies, found under trees or among shrubs and by streams. The females of some species were observed to circle round in slow flight, and then to be joined by a male. This male, provided with prey (some previously caught fly), singled out a female, and on the two flies settling for copulation, the prey is found to have been transferred to the female. When the insects, male and female, were netted on the wing before settling, the prey was also found in the net. The female sucks the prey during copulation. Mr. Colman J. Wainwright describes *Setulia grisea*, a Tachinid new to Britain, and then follow notes on the Lepidoptera of the Dale collection in the University of Oxford Museum, by Mr. J. J. Walker; notes on the British dragonflies of the Dale collection, by Mr. W. J. Lucas; and a supplementary list of Coleoptera of the Oxford district, by Mr. J. J. Walker. There is further a series of extracts from the *Proceedings* of the Entomological Society of London, which include numerous interesting bionomic observations.

These memoirs and the reports of the Hope Pro-

fessor of Zoology represent a body of useful and interesting scientific work on which Oxford University can be heartily congratulated. The excellent work done is honourable also to the science of entomology. The laws of life generally apply equally to the lower forms as to the higher, the general problems of heredity, variation, environment, &c., all receive illustration in the insect world, and such studies and observations as are recorded in these "Hope Reports" make a wide appeal to all zoologists and students of biological problems.

CYZICUS.

Cyzicus: Being some Account of the History and Antiquities of that City and of the District Adjacent. By F. W. Hasluck. (Cambridge Archæological and Ethnological Series.) Pp. xii+326; sketch maps. (Cambridge: University Press, 1910.) Price 10s. net.

MR. F. W. HASLUCK, the assistant-director of the British School at Athens, is an archæologist whose knowledge of the bypaths of travel in the Levant is extensive and peculiar. His work, too, has lain among the bypaths of antiquity rather than on its main routes. One of the pleasures of the "Annual of the British School at Athens" for some years past has been the reading of the assistant-director's articles on Frankish Greece and the Ægean Isles in mediæval days. Mr. Hasluck has devoted most of his time to the lands still under Turkish sway, and the present book is a description of what is known of a certain district of Bithynia, of which the centre was the ancient and famous city of Cyzicus.

The author modestly says that his book "lays little claim to be considered as more than a compilation, checked, where possible, by original research." It is more than this, and the original research has been so fruitful and is so genially described that we may wish, perhaps, that Mr. Hasluck had given us only his original research and had left the compilation part out. The book would not have been much smaller, and it would have been more interesting. However, this was not the plan and intention of the book, and no doubt the material derived by Mr. Hasluck from Wiegand and other recent authorities on this part of Asia Minor will be useful to English readers. Wiegand's drawings of the Roman bridge at Sultan Chair, reproduced by Mr. Hasluck, should be of interest to architects. It is a fine and dignified design, worthy of modern adaptation.

The book, part original and part compilation, then, is a very exhaustive monograph on Cyzicus and its district, followed by a very complete bibliography. Mr. Hasluck treats first of topography, in which the results of his own journeys are included, and various new identifications of ancient sites are made. Then he passes to the history, religion, and ancient government of Cyzicus, followed by a very useful index of inscriptions. Mr. Hasluck's photographs are good, and it is a pity there are not more of them. The plans are mostly from Wiegand.

Mr. Hasluck traces the history of Cyzicus from its foundation to the present day, when its site is a waste of meagre and uninteresting ruins, and only the name Bal-kiz preserves the ancient Παλαιὰ Κύζικος In Turkish, *Bal-kiz* means "Honey-Maid," so naturally the Moslem mind identified this *Bal-kiz* with Balkis, the Queen of Sheba, who visited Suleiman the Wise; and the ruined Roman amphitheatre, turned into a castle in Frankish days, was for the Turks Balkis Serai, "the Palace of Balkis." This is one of the many curious little bypaths into which Mr. Hasluck leads us.

The only criticism one has to make is that Mr. Hasluck is too much inclined to rely upon classical authority for his early dates. He accepts the traditional date (756 B.C.) for the foundation of Cyzicus, although there are serious grounds for thinking that this, like all the generally accepted dates of the founding of the oldest Greek colonies, is too early. The traditional year of the second colonisation, 675 B.C., is a more probable date for the first. After all, these dates rest on no more trustworthy grounds than do the Greek dates for the kings of Lydia, which are known to be all wrong. It is odd to find Mr. Hasluck quoting the Eusebian date for Ardys, which is nearly a century and a half too high. Surely, nowadays, we should quote the certain date, known from the contemporary Assyrian records, which place the reign of his father Gyges between 675 and 650. If the "second" founding (which one may think was probably the first and only founding) took place in 675, it can hardly have been due, as Mr. Hasluck considers, to the friendliness of Gyges to Greek colonisation, as in 675 he had hardly been any time upon the throne. However this may be, it is in any case certain that Ardys became king about 650, and Eusebius is really too doubtful an authority even to be mentioned.

In the chapter on religion we find an instance of the same indifference to the results of Oriental research in an adhesion to the old fable of the Sinopean origin of the god Serapis, who is accepted by Mr. Hasluck as originally a native deity of northern Asia Minor (p. 227). Letronne long ago explained the genesis of this story, first circulated by Plutarch and then copied by Tacitus. Sarapis was a purely Egyptian deity, Asar-Hapi, Osiris-Apis, represented at Alexandria in a Greek Zeus-form. The seat of his cult at Memphis seems to have been called *Si-n-Hapi*, "Place-of-Apis," *Sinopion* in Greek. Hence the Sinope story.

However, Mr. Hasluck may be excused for not knowing this fact, notwithstanding that attention was directed to it in an article (by the late Mr. P. D. Scott-Moncrieff) on Plutarch's "De Iside et Osiride," which lately appeared in the "Journal of Hellenic Studies." Classical archæologists should, no doubt, be a little more open than they often are to the reception of Egyptological and other Oriental knowledge; but they cannot be expected to be always aware that some time-honoured Greek belief or other about Oriental matters has long been exploded.

The point is a very minor one in this book, and has

only been expatiated on here in order to point a moral. On his main subject Mr. Hasluck is absolutely trustworthy, and has produced a book which is a credit to himself, to the British School at Athens, and to the University of Cambridge.

H. R. HALL.

RADIOTELEGRAPHY.

Jahrbuch der drahtlosen Telegraphie und Telephonie. Band iii., Hefts 1–6. Pp. 1–634. (Leipzig: Johann Ambrosius Barth, 1909–10.)

FOR those who wish to keep pace with the rapid theoretical and practical progress that is being made in wireless telegraphy, this Jahrbuch is almost indispensable. It contains full accounts of many important researches, abstracts of others, and each number gives a very complete bibliography of the literature on the subject, also a brief account of recent patents.

Glancing through the pages of the present volume, we are impressed with the great improvements that have been made in quantitative measurements. The phenomena dealt with are exceedingly complicated, and as a time interval of one-millionth of a second is long, the inertia of ordinary matter makes it mechanically impossible to follow the rapid changes that take place in an oscillating circuit. Fortunately, the inertia of a kathode stream is practically negligible, and the Braun tube is, in consequence of this, very frequently used in researches on electrical oscillations. This instrument has been utilised by Vollmer in an elaborate investigation of the Poulsen arc (pp. 117–74, 213–50), and by Roschansky in a shorter series of experiments on spark gap resistance (pp. 21–57). From both papers it is evident that much remains to be done before a satisfactory *quantitative* theoretical explanation of the behaviour of arcs and sparks can be given.

There are several papers on the mathematical theory of coupled circuits. Mackü criticises the work of Cohen, discusses the theory of the Fischer method for examining the two waves in coupled oscillators, and gives some approximation formulæ of his own. Berthenod compares direct and inductive coupling mathematically, a problem of particular interest at the present moment.

The problem of long-distance transmission has brought forth many mathematical discussions of the diffraction of electromagnetic waves; one by H. Poincaré appears in the present volume. But it is doubtful whether diffraction plays a very important part; a highly conducting layer of air in the upper regions of the atmosphere would probably be a much more important factor. Very little has so far been published regarding long-distance transmission. Surely a large number of valuable statistics must have been gathered during the past few years at powerful wireless telegraph stations, like Marconi's transatlantic stations, the publication of which would be of the greatest theoretical and practical interest.

Only three papers appear from English men of science—one by Lodge and Muirhead on "The general principles of syntonic wireless telegraphy"; a second by Fleming, "Some quantitative measurements in radiotelegraphy"; and a third by N. Campbell on "The æther."

Wireless telegraphy seems to be very much neglected by the technical colleges in this country; which is most regrettable, as probably in no other branch of engineering is it so essential that an original investigator should have such a very thorough grasp of the fundamental principles of physics.

MODERN ENGINEERING ACHIEVEMENTS.

Engineering of To-day. By T. W. Corbin. Pp. xvi+367. (London: Seeley and Co., Ltd., 1911.) Price 5s. net.

THE author of this book has set himself the task of giving a popular account of the present developments of engineering science, illustrating his text with diagrams and photographs, and, although he has not attempted to make any rash forecasts, yet he has indicated the directions in which future developments are likely to occur.

The first few chapters are devoted to the various sources of power; the steam engine, the gas engine, and hydraulic motors, are all in turn dealt with; then follows a chapter on how this power is transmitted, special attention being devoted to electrical methods. The author next treats of the materials used by the engineer, and modern methods of manufacture. In describing the cantilever system of bridge construction, it is a pity that the author did not adopt the elegant illustration given by the late Sir Benjamin Baker in the course of a popular lecture on the design of the great structure across the Firth of Forth. Ship construction is explained somewhat fully, and a clear account is given of the structural design of most of the leading types of passenger and cargo boats; to ships of war a special chapter is devoted, and, as an illustration of the most modern type of battleship, the author has selected the *Minas Geraes,* recently built by the firm of Sir W. G. Armstrong, Whitworth and Co. for the Brazilian Government. Submarine work and submarine diving form the subject of another chapter.

A short account is given of the filtration of water prior to its distribution to the consumer, but no mention is made of the system of mechanical filtration, which has recently been extensively adopted. As an illustration of a great water scheme, the author has selected the Coolgardie water supply, probably the most daring scheme ever conceived, and one which has proved entirely successful.

Three excellent chapters are those devoted to railways and their work; a description is given of the construction of a modern express locomotive, and details as to the signalling appliances which have to be adopted in order to secure the safety of trains on lines crowded with traffic.

That the book is quite up to date is proved by the

chapter entitled "The Conquest of the Air," in which accounts are given of the latest types of dirigible balloons and of aëroplanes.

In the concluding chapter the author attempts to discuss the engineering of to-morrow. He rightly points out that for many years to come the energies of the engineer will be directed mainly towards the problem of the "utilisation of waste materials and waste forces." The author suggests that in the utilisation of the heat and energy given out by the sun a solution may be found for the difficulty which will arise when the world's coal supply is exhausted. All such proposals are, however, still mere ideas.

The author of this book set himself a difficult task, and he has accomplished it in a satisfactory manner.

T. H. B.

TECHNICAL MYCOLOGY.

Technical Mycology: The Utilisation of Micro-Organisms in the Arts and Manufactures: A Practical Handbook on Fermentation and Fermentative Processes for the Use of Brewers and Distillers, Analysts, Technical and Agricultural Chemists, Pharmacists, and all interested in the Industries dependent on Fermentation. By Prof. F. Lafar. Translated by Charles T. C. Salter. Vol. ii., "Eumycetic Fermentation." Part ii. Pp. x+191–748. (London: C. Griffin and Co., Ltd., 1910.) Price 18*s*. net.

THOSE who worked with the first volume, and the first part of the second volume of Lafer's "Technical Mycology," have waited, with some little impatience, for the appearance of the second part of the latter volume. We have waited our seven years, but have, at last, been rewarded by a work that will be of considerable value to those who are working at eumycetic fermentation, the consideration of which is continued by Prof. Lafar and by a number of experts, each of whom has undertaken to treat a part of this question.

In an introductory section Prof. Lafar himself takes up the general question of yeast nutrition and yeast culture, and brings his subject well up to date. An interesting chapter on variability and heredity in Saccharomycetes may have a much wider bearing than in its application to brewing. Our author points out the importance of the presence of certain mineral foodstuffs, and indicates the possible sources of organic foodstuffs, laying special stress on the sources of nitrogen and on the oxygen requirements of the yeast cell. Here, in connection with Hansen's experiments, he indicates the most favourable conditions for cell reproduction, and the oxygen requirements for both cell-reproduction and respiration. Then follows a description of the effect of copper and its salts, inorganic acids and salts, organic stimulants and poisons, and of alcohol itself upon the yeast cells. Some part of this is repeated by Albert Klöcker, of Copenhagen, who, treating the matter from a somewhat different point of view, gives a very good account of the life-history and variability of the Saccharomycetes, and describes fundamental researches into the life-history of these organisms, temporary variations, and the production of sporing and non-sporing forms, and the development and maintenance of these varieties under various definite conditions. Klöcker also contributes an interesting and full classification of the families Saccharomycetaceæ and Schizosaccharomycetaceæ, which will probably be an accepted classification for some time to come.

In a chapter on the morphology and subdivision of the family Aspergillaceæ, Prof. Carl Wehmer gives an account of the saccharification of starch, acid fermentation, formation of alcohol, and the degradation of proteids and their derivatives by the members of this family. Special articles are also contributed by Prof. G. Lindau on "*Cladosporium herbarum* and *Dematium pullulans*"; by Dr. H. Will on "The Torulaceæ, Pink Yeasts and Black Yeasts"; by Prof. Richard Meissner on "Mycoderma or 'Mother of Vinegar'"; by Prof. H. Müller-Thurgau on "The History, Morphology, and Fermentation phenomena of *Saccharomyces apiculatus*"; by Dr. H. Wichmann on the Monillæ and Oidia; and, in the section devoted to enzymes and enzyme actions of yeast, by Dr. Rudolf Rapp on "Alcoholase," by Dr. Arminius Bau on "The Chemistry of Alcoholic Fermentation and on the Enzymes Decomposing the various Sugars"; whilst Dr. Lafar and Dr. M. Hahn close the work with a chapter on "Endotryptase and Philothion."

The new method of treatment, though it takes away somewhat from the continuity of the story, has many advantages in so far that each part is treated by a special authority, and has thus been brought more fully up to date than would have been possible had Dr. Lafar attempted to cover the whole ground single-handed

The subject-matter of the latter part of the work, dealing with enzymes and enzyme actions of yeast, has passed through such rapid transformation within quite recent years, and is still being so highly developed that it would be impossible for any single writer to keep pace with the enormous numbers of publications that have appeared, and to summarise at all adequately the work thus presented to botanists and chemists. How difficult this would have been may be gathered from the bibliography given at the end of the book, a bibliography which covers more than 130 pages, each page containing from twenty to forty titles of papers. In this volume is contained a very full index of the whole work, without which the reader will have some difficulty in gaining access to the material contained in the earlier published volume and part. The translator has done his share of the work well; the illustrations are good, and the general appearance of the book corresponds very closely to that of the earlier issues. The completed work is far more valuable than it is in the individual parts, and we strongly advise those who take an interest in the technical subjects dealt with in this part to read it, and then keep it for reference alongside the others.

COLLOID CHEMISTRY.

An Introduction to the Chemistry of the Colloids. A Compendium of Colloidal Chemistry for Students, Teachers, and Works Managers. By Dr. V. Pöschl. Translated from the second, enlarged, German edition by Dr. H. H. Hodgson. Pp. iv+114. (London: C. Griffin and Co., Ltd., 1910.) Price 3*s*. 6*d*. net.

THIS short work is well described in its title as a compendium of colloidal chemistry. Struck by the growing importance of this branch of chemical science, the author has endeavoured to provide a brief summary of the chief characteristic properties and modes of preparation of colloids, as well as to indicate some of the more important phenomena in the production of which colloidal substances are concerned.

The chemical methods for the preparation of colloidal solutions of the hydroxides, sulphides, and metals are described in some detail, together with the properties of the resulting hydrosols, special attention being paid to gold and silver, the study of which has done so much to advance our knowledge of the colloids. The electrical methods, due to Bredig, for the production of metallic hydrosols are also well described, whereas the precipitation methods by which colloidal solutions of sodium and barium salts have been obtained are not mentioned.

The character of the work is incompatible with much discussion of the numerous knotty points which must inevitably arise in any account of the various theories of the colloidal state, but a clear description of these theories is given, great stress being laid on the positive evidence afforded by the ultramicroscope that colloidal solutions are not homogeneous. Attention is also directed to the important fact that many substances, a list of which is given, are known both in the crystalline and colloidal forms, and that the colloidal state is not necessarily a property only of substances possessed of a large molecule and complex chemical constitution, but may also be associated with quite simple substances, the nature of solvent, or, as it is better termed, the dispersion medium, being frequently the deciding factor.

Perhaps too little stress is laid on the electrochemical relations of colloids, and the important subject of the mutual precipitation of colloids of opposite electrical sign is dismissed in a single line.

The concluding sections on the importance of colloidal chemistry in various branches of chemistry and in other sciences indicate very clearly how much assistance these are deriving from the realisation of the fact that many familiar phenomena can only be adequately understood in the light of our knowledge of the colloids.

On the whole, it may be said that the purpose of the author in compiling this account of the colloids has been fully realised, and that the reader will gain a good idea of many of the points of interest connected with this difficult and important subject.

A. HARDEN.

OUR BOOK SHELF.

An Introduction to the Study of Metallurgy. By Sir W. C. Roberts-Austen, K.C.B., F.R.S. Sixth edition, revised and enlarged by F. W. Harbord. Pp. xv+478. (London: Charles Griffin and Co., Ltd., 1910.) Price 18*s*. net.

THE appearance of a new edition of Sir William Roberts-Austen's "Introduction to the Study of Metallurgy," which has been out of print for some time, is to be heartily welcomed, as no other book adequately fills its place in metallurgical literature. Since its first publication there have been vast advances in pyrometry, metallography, and in metallurgical processes, advances which were only partially dealt with in succeeding editions. In this the sixth edition special attention has been given to the results of recent research and metallurgical progress; the chapter on pyrometry has been rewritten, a new chapter on metallography has been prepared, and in the chapter on furnaces, descriptions and illustrations of typical modern furnaces and appliances have been introduced to replace those which are no longer in general use. This chapter also contains an extremely useful account of the construction, modes of working, and uses of the three chief types of electric smelting furnaces.

A valuable addition, the thermal treatment of certain industrial alloys, has been made to chapter iv., which in previous editions was confined almost entirely to the thermal treatment of steel.

The book is intended to give a systematic course of study in the fundamental principles on which metallurgical processes are based, and the success of their various operations depend; and for this it is admirably adapted. It will be conceded by all that without this knowledge the difficulties and irregularities which arise in metallurgical practice can be, if at all, but imperfectly contended with.

The information which is given on the subjects dealt with, although necessarily brief in some cases, is set forth with remarkable clearness, and is thoroughly trustworthy and up to date.

The new edition is an excellent piece of work, and Mr. Harbord deserves the congratulations of metallurgists for having brought this valuable text-book into touch with the times. It is indispensable not only to students, but to all who are engaged in practical metallurgical work. W. G.

Untersuchungen über die Zoogeographie der Karpathen. (Unter besonderer Berücksichtigung der Coleopteren.) By Karl Holdhaus and F. Deubel. Pp. vi+202, and map. (Jena: Gustav Fischer, 1910.) Price 8 marks.

IN this important and carefully written work Prof. Holdhaus analyses chiefly the Coleoptera of the Carpathians, with special reference to the influence of the Glacial period on the Alpine fauna of Europe. We may perhaps quote a few words from his introduction to make his starting point clear, though possibly the case is a little overstated, in view of the circumpolar fauna and flora:—"During the Glacial period all life was annihilated in northern Europe. The animals at present inhabiting north Europe are post-Glacial immigrants. The remarkable impoverishment and monotony of the northern fauna—especially the absence of a typical mountain fauna in Fenno-Scandia—seems inexplicable except from this point of view. In central and southern Europe the influence of the Glacial period is chiefly visible in the mountain fauna."

Prof. Holdhaus commences by discussing the geological history of the Carpathians, and their climate and vegetation. Then he proceeds to discuss the distribution of the Coleoptera of the Carpathians, and the districts which they inhabit, the age and origin of this fauna, and how far it has been influenced by

the Glacial period, especially as compared with the fauna of the Alps. Another chapter deals with the distribution of mammals, reptiles, amphibia, mollusca, &c., in the Carpathians, followed by lists of Coleoptera (by Holdhaus and Deubel) found in different districts in the Carpathians, with notices of the surroundings. The map illustrates the glaciation of the eastern Alps and Carpathians during the Ice period, and the range of the blind mountain beetles. These beetles are a specially interesting group, of limited range, in the Austrian Alps. Some of them are cave species, while others inhabit the open.

Many interesting subjects are discussed by Prof. Holdhaus, which we have no space to allude to, but he has not forgotten to take account of fossil and amber Coleoptera, and his remarks on what he calls "Massifs de refuge" (districts south of the Alps to which he believes the mountain species retreated during the Glacial period) also seem to deserve special attention.

Mosses and Liverworts. An Introduction to their Study, with Hints as to their Collection and Preservation. By T. H. Russell. New and revised edition. Pp. xvi+211+xiii plates. (London: Sampson, Low, Marston, and Co., Ltd., 1910.) Price 4*s*. 6*d*. net.

THE speedy demand for a second issue of Mr. Russell's book testifies to its value and usefulnes as a guide to the study of mosses and hepatics. The introductory portion is all that can be desired, and the student who conscientiously masters this portion will be in a position to pass on to more advanced books dealing with the same subject. The author lays much stress on the point that he is specially anxious to use simple language, fearing that scientific words might act as a deterrent to the study. With this frequently expressed idea we do not quite agree; the true value of a scientific term consists in the fact that, when once grasped, it stereotypes the particular structure in a single word, whereas a sentence in English may convey but a very vague idea of the structure in question. As an example, the term *archegonium* defines a definite structure, which is said to be "the fruit-bearing organ," which it certainly is not. The species given as examples are well chosen, and cover all the structures peculiar to mosses and hepatics.

The detailed account of habitats, and the stress laid on their importance, are features to be commended, as too frequently the student is encouraged to snatch a fragment from anywhere, put it into a tube containing methylated spirit, and only commence serious study when viewing it under a compound microscope. The chapters on collecting, storing, and the preparation of mounted specimens for microscopic work are very full, and are obviously the outcome of much practical experience.

Thirteen whole plates of excellent figures add much to the value of the book, which can be confidently recommended as a stepping-stone to the study of mosses and hepatics.

The Social Guide, 1911. Edited by Mrs. Hugh Adams and Edith A. Browne. Pp. xxxviii+252. (London: A. and C. Black, 1911.) Price 2*s*. 6*d*. net.

INFORMATION is given in this work of reference not only about occupations for leisure days and hours, but also concerning more serious pursuits. The diary with which the volume begins includes the meetings of the Royal Geographical Society and of the British Association among scientific societies, and the anniversary dinner of the Royal Society. Though it is sometimes a little difficult to understand the principle of selection for the contents of the volume, we notice the activities of the Royal Institution, the Royal Society of Arts, and the Zoological Society are described.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

A Kinetic Theory of Gravitation.

THE subject of Mr. Brush's article in NATURE of March 23 (p. 129) is certainly of profound interest, and will continue to be so until the problem as to the nature of gravitation is solved. Meanwhile, a few questions raised are comparatively simple. Anyone asked, Where lies the energy of a raised weight? must surely reply, "In the æther," *i.e.* in the medium, whatever it is, that is driving the weight down towards the earth. A critic who either doubts or asserts this will not be confused—as Mr. Brush suggests he will be—by the suggestion that the weight might be raised so high as to reach the neutral point between earth and moon—a suggestion which carries with it the tacit questions, "Where is the energy now?" and "What has become of the work done?"—for this case is no more troublesome than the case of a weight raised and hung on a hook. Something—some opposition force—sustains the weight, *i.e.* opposes the pull of the earth, and it matters little whether the opponent be a shelf beneath it or the moon above it. The important thing to understand is the nature of the downward propelling force—indeed, of both the upward and the downward force—in either case.

The question whether the energy of a raised weight is potential or kinetic is of little or no importance. The energy is certainly potential, according to our definition of potential. So is the energy of a strained spring: for there also the atoms are separated against their mutual (cohesive) attraction, and there again the energy really resides in the æther. But that all energy may turn out to be ultimately kinetic—when we come to understand what elastic stress fundamentally is—that proposition is not negatived in the least.

Mr. Brush proposes a shadow theory of gravitation, a modification of Le Sage's theory except that the pressure is supposed due to the non-syntonic impact of waves travelling in all directions, instead of to a bombardment of utterly minute particles flying at random. There is nothing new in a shadow theory, and all such theories are faced with the difficulty of plausibly explaining the absence of noticeable screening—a difficulty which is bound to reduce them to acquiescence in an approximation.

The contribution which Mr. Brush makes to the discussion is the suggestion that the supposed gravitational æther-waves are the result of accumulated thermal radiation from all past and present suns, the wave-lengths having automatically increased during their long storage.

To this view several objections might be urged—one of them being that in that case the constant of gravitation would be secularly increasing; another, that it should be greater in a hot enclosure, say the interior of a sun, than elsewhere; but a more salient obstacle is raised by the inquiry as to which is cause and which is effect. How did the bodies get hot and so radiate? Was not their heat perhaps due to their having clashed together with gravitational energy itself derived from the æther?

The fact is that every question concerning *origin* involves us always in insuperable puzzles, and that is just the main difficulty about gravitation. An atom of matter, by its very existence, sets up a fixed stress in the æther, varying directly as the mass and inversely as the distance—that is only another way of stating the law of gravitation; we are trying to understand the nature and cause of that stress. It appears to be one of the fundamental properties of matter, and until we can understand what is meant by the generation or destruction of an atom—*i.e.* of an electron if that is the fundamental unit—we are hardly likely to understand its gravitational influence more than any other of its fundamental properties—including, perhaps, existence itself.

Let this not be understood as a negative prediction or estimate of impossibility—such predictions are always absurd; it may be that when the structure of an electron

is understood, we shall see that an "even-powered" stress in the surrounding æther is necessarily involved. What I do feel instinctively is that *this* is the direction for discovery, that what is needed is something internal and intrinsic, and that all attempts to explain gravitation as due to the action of some external agency, whether flying particles or impinging waves, are doomed to failure; for all these speculations regard the atom as a foreign substance—a sort of "grit" in the æther—driven hither and thither by forces alien to itself. When, some day, we understand the real relation between matter and æther, I venture to predict that we shall perceive something more satisfying than that. Oliver Lodge.

Visual Sensations from the Alternating Magnetic Field.

There is no necessity to look to suggestion or other abstruse causes to account for this phenomenon. The electric currents induced in the head are quite sufficient to produce the effect.

As I pointed out in a letter to *The Electrician* on April 22, 1910, electrodeless currents in the body produced by electromagnetic induction from a coil carrying so-called high-frequency currents have been in use in medical practice for some years.

Employing as primary a coil of wire of many turns, and some 2 feet in diameter, carrying high-frequency currents from the discharges of a large battery of Leyden jars, and using as secondary the body and the two arms bent so as to form a circle, sufficient current can be induced in the circuit formed by the arms and body to light a miniature incandescent lamp connected between the two hands, or a sufficient difference of potential can be produced between the two hands to cause small sparks to pass visibly between them when they are held near together.

It is easy to produce the visual flickering effect by passing through the head the current from an ordinary continuous-current magneto generator, such as is supplied with the Evershed ohm-meter. One terminal of the generator should be held in one hand, while a wire from the other terminal should be held in the other hand in contact with a small piece of wet sponge, and the latter pressed lightly on one side of the head just behind the eye. If the generator handle is then slowly turned (and it is wise to turn it slowly to avoid unpleasant results) the flickering effect will at once become very noticeable, and as the frequency of the flicker increases with the speed of revolution, it apparently is connected with pulsations in the current due to the slow revolutions and the few segments on the commutator. The current through the head must be very small, as the bulk of that generated goes from hand to hand through the arms and body.

I first noticed this phenomenon some fifteen years ago when treating myself electrically for neuralgia, but I fancy that the effects of electric currents on vision have been known much longer than that.

Passing electric currents through the head in certain directions also produces a metallic taste in the mouth.

The Angular Speed of Rotation of a Long-enduring Prominence.

Thanks to the note contained in the "Astronomical Column" of Nature of March 9, my attention has been directed to the very interesting article under the above heading in the January issue of the *Astrophysical Journal*.

The prominence Mr. Evershed describes is the same as that under consideration in my letter contained in Nature of February 23, and of which disc-spectroheliograms were given in the issue of February 2 in connection with the reproduction of M. Deslandres' address of June 12, 1910. The Meudon spectroheliograms add thus a plate to the series enumerated by Mr. Evershed on p. 3 (*Astrophysical Journal*, No. 1, vol. xxxiii.), and an additional date is further added by the spectroheliogram taken at Meudon on April 15, 1910. Both are beautifully reproduced in the fine memoir forming vol. iv. of the *Annales* of the Obs. d'Astr. Physique de Paris, of which M. Deslandres is the author.

The Meudon spectroheliograms seem greatly superior to those accompanying Mr. Evershed's article in the *Astrophysical Journal*, undoubtedly on account of the excellent and original instrumental combination resorted to by M. Deslandres, which aims at *the absolute isolation of the central rays* K_3 *of calcium or of* $H\alpha$ *of hydrogen*. Comparing the Meudon spectroheliogram of March 21 with what Mr. Evershed says (p. 5) as regards the appearance of the dark formation under discussion, one cannot help being struck by the seeming divergence of the evidence. Mr. Evershed says:—"On March 21 it reappears as a *vague* and *ill-defined* dark mass." Further, he states on March 25 that "the northern arm can indeed be faintly traced for a much greater distance in a vast circular sweep towards the eastern limb." Reverting, now, to the Meudon spectroheliogram of March 21, the dark mass is seen of quite immense breadth longitudinally, no fewer than 5 degrees, is pronouncedly distinct in its entire vast extent also latitudinally, shows well-defined western and eastern contours, both convex towards the west, and also shows the narrow extension towards the N.N.E. quite distinctly. This great difference of what the Kodaikánal plate for March 21 shows as compared with the plate taken on the same day at Meudon, creates in my mind a doubt as to the actuality of what Mr. Evershed suggests on p. 6, viz. the disappearance in its entirety of the dark formation between March 25 and 26.

With due deference to the able observer, I venture to say that possibly inaccurate relative setting of first and second slits, along with insufficient dispersive power or other optical inferiority to the Meudon spectroheliograph, has not allowed the Kodaikánal plates to be so sharp and rich in detail as the Meudon plates. This is further suggested by the striking absence on the Kodaikánal plates of many conspicuous dark calcium flocculi, which during those days infested the sun's disc all over, yet, of course, there is the possibility of their temporary absence; but, on the other hand, on each of the successive appearances of the large prominence on the east or west limbs, the formation exhibited the striking feature of a dark, flat cloud hovering over the bright prominence-range along its entire latitudinal extent, as described in my letter, suggesting, therefore, continuity rather than intermittent or "puffing" action. The Meudon plate taken on April 15 clearly shows the re-entry into the disc of the dark formation, with a more acute apex directed towards the west than during the previous transit, and the N.N.E. directed arm is not yet absent as it is on the Kodaikánal plate of April 18.

Incidentally, another exceptional feature of the sun's disc should be mentioned which was strikingly on view during April and May, 1910, viz. the fine circumpolar wreath of dark flocculi in the south. A formation of this kind goes a long way towards explaining the previously puzzling experience of observing for many days in succession prominences at apparently the same position-angles in comparatively low latitudes. These prominences are, as a rule, of the quiescent, brushy, and rather dull type. Albert Alfred Buss.

The Flow of Thin Liquid Films.

In the very interesting letter by Mr. W. G. Royal-Dawson in Nature of March 23 on the above subject, the peculiar character of the stream-lines round a moving air bubble compared with those round a fixed solid obstacle may seem to some to require an explanation. As the writer of the letter offers none, may I be permitted to state what appears to be the cause of the conflicting currents shown in Fig. 4 of Mr. Royal-Dawson's letter?

It is stated that on pressing the cover-glass the bubble seems to increase in size. From this we may conclude that it is in contact with the glass surfaces top and bottom. It will therefore be more or less anchored. The result of this is that if it is to move it can only do so by the formation of new film on the front, or by the old film which is collecting in the rear from the top and bottom of the bubble moving to the front. As water offers

resistance to the formation of new film, the film-tension in the front will be greater than in the rear, and the film will be dragged from the rear to the front of the bubble, and in its movement will carry the water in contact with it, thus causing the forward current *a*. As the supply of film has to travel in a narrow stream in the middle of the space between the two glasses, it will flow with considerable velocity, as it has to provide film for all the area dragged on by contact with the glass surfaces.

Insect Intelligence.

My friend Prof. Hughes's story about a fox's cleverness in getting rid of his fleas induces me to recount an instance of insect intelligence which I witnessed about fifty years ago at Elmstead in Essex, a place teeming with insect life. There was a narrow border round the wall of my house; on this I noticed one day a large fly of the ichneumon family straddling over and dragging a green caterpillar bigger than itself. I watched it crawling for some thirty or more yards round an angle of the house until it came to a corner protected by a projection of the wall. Here it deposited the caterpillar, and removed one by one a little heap of small stones. This disclosed a cylindrical hole in the ground, into which the fly descended tail first, dragging the caterpillar after it. It then came out, and again went down, apparently stamping the caterpillar close, and may probably at the same time have laid an egg. It then came up, replaced the stones so as to hide the orifice, and flew away.

This probably was only an instance of the mode of proceeding of the whole species, but notice what it involves. The insect must have dug the deep hole and hidden the entrance to it carefully for future use, and it must have remembered its position so as to find it again from whatever quarter where it may have chanced to find its prey.

Graveley, Huntingdon. Osmond Fisher.

Reflection of Ultra-violet Rays by Snow.

Allow me to make the following short statement in the columns of Nature.

During the past winter we have had frequent snowfalls here in Switzerland, these being followed very often by bright sunshine. I availed myself of these occasions to determine to what extent the spectra of sunlight, reflected by snowfields, reaches into the ultra-violet. To this end I took numerous photographs of the spectrum produced by this reflected light, the angle being 45°. The time of exposure varied from 1 second to 20 seconds, with a slit opening of 0·05 mm. The results showed that this spectrum of reflected sunlight reaches up to 295 $\mu\mu$. The tests were made between 10 and 12 o'clock a.m. at an altitude of 630 metres above the sea-level.

Comparing the results with those of Cornu, we must conclude that the ultra-violet rays are reflected by snowfields almost in their entirety, and hence the powerful action of this light cannot be called into question. It would therefore be advisable at all times, during a period of snow and sunshine, to protect the eyes from the injurious effects of these ultra-violet rays by using glasses which will not permit these rays to pass.

Assil Cotton.

A form of cotton has been produced, by selection in the field from superior growths of Mit Afifi, which is said to be a pure strain and similar to the Mit Afifi of twenty years ago. This form is known by the name of "Assil," meaning "of pure original strain."

In order to prevent any misconception occurring that by substituting "Assil" for the present impure Mit Afifi the introduction of a new variety is advocated, it is recommended that this form of cotton be for the present referred to as "Assil Afifi."

INSURANCE AGAINST RAIN.

A scheme of holiday insurance against rain has been put forward by the Excess Insurance Company, and has been described in considerable detail in *The Times* of March 21 and 22. It applies to the period from May 1 to September 30, at a series of sixty-three sea-coast towns on the south and east of England. It is stated that the daily readings of rain gauges at the towns in question (or in some cases where there is no local observer at a neighbouring town), will be supplied to the company by the town clerks, or "culled from the lists of the Meteorological Office." Four forms of policy are proposed, designated respectively Pluvius A, B, C, and D. Policy A provides for payment for each separate week in which there is rain on more than two days, amounting on each to more than 0·20 in., and the premium is to be one-eighth of the compensation to be paid per week. Policy B provides for payment for every day on which the rainfall exceeds 0·20 in., and the weekly premium is equal to one and a half times the compensation offered per day. Policy C provides for payment for the second and each additional rain-day in a week on which the rainfall exceeds 0·15 in., and the weekly premium is equal to the daily compensation, and Policy D provides for four days, payment being made for every day on which more than 0·20 in. falls, and the premium for the four days is equal to the compensation per day.

The interest of the proposition lies in the fact that the rain for which compensation is to be paid may fall entirely at night and not affect the enjoyment of the holiday at all, and as much compensation will be paid, so far as we can judge, for a thunder-shower of ten minutes' duration yielding just more than 0·20 in. as for a day of uninterrupted rain for twenty-four hours, yielding two or three inches. As there is no necessity laid on the assured to prove damage or even to go near the place where the rain is to be measured, it is apparent that a question may arise as to whether the transaction in certain cases is legitimate insurance or mere gambling. The assured and the company are bound by the terms of the policy to accept the readings of daily rainfall supplied from a specified rain gauge as binding, but no information is given in the articles from which we quote as to the limits of the rainfall day, *e.g.* whether it is to count from 9 a.m. to 9 a.m., as in ordinary records, or from 7 a.m. to 7 a.m., as at the daily reporting stations of the Meteorological Office. No indication is given as to how the records from those stations which read rainfall to three places of decimals are to be interpreted; for instance, one observer records 0·204, where another for the same quantity in the measuring glass records 0·20; the first records 0·206 where the other records 0·21; and when the first records 0·205 the second may read 0·20 or 0·21 with equal truth; but the alternative he chooses would decide the payment or non-payment of perhaps a considerable sum as compensation.

It must also be remembered, as Dr. H. R. Mill points out in *The Times* of March 23, that in summer the rainfall varies very greatly in a short distance, and unless the assured stays very near the rain gauge he may experience totally different weather from that which it records. Here, however, the chance is even of the rainfall being more or less than is recorded—in the one case he may be damaged without compensation, in the other he may be compensated without damage. Dr. Mill considers that there are no data yet elaborated on which a fair basis for an equitable and practicable scheme of insurances against rain risks can be framed.

THE LAND OF THE HITTITES.[1]

PROF. GARSTANG has written an able and informing book on recent archæological exploration and discoveries in Asia Minor. The book is written *à propos* of Prof. Garstang's recent discovery of a Hittite palace at Sakjegeuzi (Sakčegözü), in North Syria, south of the Taurus, near the palace-fortress of Sinjirli, excavated by the Germans some years ago. Prof. Garstang has also visited Boghaz Köi, the site of Khatti, the ancient Hittite capital (lately excavated by Dr. Winckler and Makridi Bey), and other Hittite sites and monuments. The result is the present work, which sums up all that is known on the subjects of the Hittites up to date.

FIG. 1.—Sakje-Geuzi: Royal Hunting Scène. From "The Land of the Hittites."

Naturally, much that Prof. Garstang says about the Hittite monuments is mere repetition of what has already been said by others, except in cases where he is able to add the results of his own personal investigations. And the initial "Chapter on Geography" is perhaps rather tedious. The valuable part of the work consists of chapters iv. and v., the descriptions of Boghaz Köi, Eyuk, Sinjirli, and Sakjegeuzi. Chapter vi. should, we think, have been combined with chapter iii., to form a continuous history of the Anatolian civilisation. The greater part of chapter vi., "the story of the Hittites," is based upon the Babylonian cuneiform tablets discovered by Winckler at Boghaz Köi, which have thrown so unexpected a light on the history of the Hittite kingdom from the time of Shubbiluliuma, the contemporary of the Egyptian Amenhetep III., to that of Arnuanta, who was a contemporary of Meneptah, a period of two centuries (1400–1200 B.C.). The story, as told by Prof. Garstang, is worth reading by those who are not acquainted with Dr. Winckler's original publication in the *Mitteilungen* of the German Orient Society. The tale of Shubbiluliuma's wars and the intrigues which gained his purposes even more effectually than his wars sounds like a bit of mediæval Italian history. He was at the bottom of the revolt which separated Palestine from Egypt when it was seen that the pacifist fanatic Akhenaten would never use force to keep his empire. Shubbiluliuma was a most unphilosophical person; Akhenaten was, we suppose, a philosopher; he had lovely ideas. The philosopher's reign caused unheard-of misery to descend upon his unhappy country, as usual, while the unphilosophical man of action got all he wanted, and, being armed, kept his own goods in peace. *Verb. sap.*

However, they were not always strong men in Khatti, and Arnuanta was probably the last of his race. Overthrown by a great folk-wandering from Europe, his kingdom was destroyed, and as a great empire disappears from history. The small States into which it broke up preserved their Hittite characteristics for some centuries later. The palaces of Sinjirli and Sakjegeuzi belong to this later period, and Assyrian influence is seen to be strong in their art. The buildings of Boghaz Köi and Eyuk, on the contrary, certainly belong to the great period of the kingdom, though they may not, as they stand, be as old as the time of Shubbiluliuma. In their art there is no trace whatever of Assyrian influence. Prof. Garstang's account of them, and of the results of the recent diggings, is very interesting.

The photographs with which the book is illustrated are very good, but are not always exactly appropriate. This is a pity. Prof. Garstang still hankers after exploded "Mongoloid" origins for the Hittites, and even prints photographs of Egyptian representations of them to prove his point (p. 318), which do not prove it at all; while to quote pigtails as a Mongolian trait is unscientific: Frederick the Great and George III. wore pigtails, but were not Mongols. Also, one cannot see anything "Proto-Greek" in the types shown in the companion photograph opposite the same page. What is "Proto-Greek"?

FIG. 2.—Dimerli: a fallen Lion. From "The Land of the Hittites."

Prof. Sayce's introduction is interesting in view of the fact that he and the late Dr. Wright were the pioneers of archæological theory in this field, based on Perrot's admirable description of the monuments. Prof. Sayce is now engaged on the congenial task of deciphering the Hittite hieroglyphics. Prof. Garstang tentatively accepts some of Prof. Sayce's inter-

[1] "The Land of the Hittites: an Account of Recent Explorations and Discoveries in Asia Minor, with Descriptions of the Hittite Monuments." By Prof. John Garstang. Pp. xxiv+415. (London: Constable and Co., 1910.) Price 12s. 9d. net.

pretations, but the historians mostly seem to prefer to wait yet awhile before adopting his system definitely.

We hope that Prof. Garstang will make further discoveries in the Hittite lands, and can wish him no better luck than that he may speedily render his present book obsolete and out of date. H. H.

MELANESIANS AND POLYNESIANS.[1]

THE veteran missionary who writes this book lived for more than twenty years on the islands of the Pacific, at the time—a generation ago—when the peoples of the western Pacific were scarcely known, when

> ". . . Old and New
> Weltered upon the border of the world."

Much of his time was spent in New Britain, more in Samoa, and the natives of these places are the people whom he means when he speaks of Melanesians and Polynesians. Dr. Brown has also visited the New Hebrides, Santa Cruz, New Ireland, New Hanover, New Guinea, and the atolls of Ontong, Java, and the Tasman group. In the introduction the author disclaims "pet theories"; nevertheless he gives us (pp. 15–17) the theory as to the origin of the Melanesian and Polynesian races, which he published in the *Journal* of the Anthropological Institute in 1887. Much water has flowed under the bridges since then, and it is at least a pity that Dr. Brown does not discuss (except briefly in the concluding chapter) some of the facts which do not support his views.

A certain looseness of terminology, most pronounced in the pages referred to, also crops up in other parts of the book. Considering especially the most valuable part of the book, that dealing with Melanesia, it is obvious that Dr. Brown has given us a record of what he himself saw or was told during the five years he spent in New Britain, but with the exception to be presently noted he has made no attempt to correlate his own observations with those of other observers, nor does he supplement them by considering the work of others, even when they deal with the very ceremonies he describes. Thus it comes about that the value of one of the most interesting chapters in the book, that dealing with secret societies, is lessened, for though it gives an account of the Dukduk, no mention is made of Parkinson's work. On the other hand, Dr. Brown has not hesitated to avail himself of information given him by colleagues, or when necessary to seek their assistance. These remarks indicate the scope of the work and its limitations, which will be felt by few except specialists working at the history of the Pacific.

Fish Trap, New Britain. From "Melanesians and Polynesians."

A more detailed examination of the contents of the volume shows that it contains a large amount of new information, not only valuable in itself, but bearing also on work being done at the present time, or which must be done in the near future. There is an extremely interesting account by an eye-witness of the death and cremation of the celebrated Shortland chief Gorai, whose importance may be gauged by the fact recorded by Guppy, that the houses of his wives and children occupied more than an acre of ground.

Several interesting examples of the widely-spread Melanesian custom of burial, accompanied by the removal and preservation of the skull of the deceased, are recorded. On Duke of York Island the body of a chief or person of importance was exposed on a specially built platform until the head could be detached, when it was preserved by the

[1] "Melanesians and Polynesians," their Life-histories described and compared. By George Brown. Pp. xv+451. (London: Macmillan and Co., Ltd., 1910). Price 12s. net.

nearest relative, while the remains were buried in the house. On Ysabel (Solomon Islands) and also in Aneityum (New Hebrides) the body was buried in such a position that the head could be severed from the trunk, which was not itself exposed. At Ysabel the process was accelerated by lighting fires round the exposed head, from which the scorched flesh was easily peeled. At Aneityum female mourners watched the head until the soft tissues had decomposed. A special interest attaches to both these methods, since they contrast with the disposal of the dead by cremation practised in some of the western Solomons and New Ireland, while they agree in principle and in some degree in detail, with the methods of inhumation accompanied by the preservation of the skulls in vogue among the archipelagoes lying off the eastern extremity of New Guinea. These facts support a view held by the reviewer that the inhabitants of the Solomon Islands will be found to be divisible into two ethnic groups, the dividing line falling somewhere in the neighbourhood of the line of political division.

Dr. Brown mentions that on his early journeys in New Britain he was able to buy fowls of a small white breed in large numbers, and he suggests that these were indigenous. The interest of this observation is greatly increased by the fact that in many parts of eastern British New Guinea the natives maintain that thirty or forty years ago they possessed a breed of pure white fowls.

No praise could be too high for the plates with which this book is abundantly illustrated. One picture shows four men of the remote islet Lua Niua (Ontong Java), who speak a language "very closely related to the Samoan." So far as the writer knows this is the first adequate portrait to be published of these Polynesians, stranded long ago in Melanesia, who although they have retained their Polynesian features appear to have come into intimate contact with Melanesians since, as Dr. Brown informs us, they are divided into two exogamous classes. An alternate explanation favoured by Dr. Brown is that they are descended from a group of exogamous castaways from the Ellice group, who, it is assumed, were derived from Samoa at a time when that island was inhabited by a people having an exogamous clan organisation.

Two unfortunate slips occur in the description of the plates. The masks and figures shown in the upper figure facing p. 238 are from New Ireland (not from New Guinea), and the two masks facing p. 316, also attributed to New Guinea, certainly do not come from there. An insufficient index gives an inadequate idea of the real value of the book. C. G. S.

THE BUSINESS SIDE OF A UNIVERSITY.[1]

UP to the present time the development of the American university system has proceeded mainly by the multiplication of universities, and by increase in their endowments. The cost of university education has, however, steadily risen everywhere; and while it has been possible up till now to provide for expansion by increased contributions of funds from outside, it is clear that a limit exists to the possibilities of further increase. It follows that the question as to whether the efficiency of American universities can be increased by a better use of their existing resources is an important question which may become urgent in the future, even if it has not done so in the past.

Under the auspices of the Carnegie Foundation for the Advancement of Teaching, a report has been drawn up on "Academic and Industrial Efficiency." The author, Mr. Morris Llewellyn Cooke, claims to have studied the problem practically exclusively from the point of view of a business man, while freely admitting that there are other aspects of the question not dealt with in his report. In order to collect information, he visited eight universities and colleges, and in every case chose the department of physics for his inquiries, on the ground that the conditions prevailing in this department might be regarded as typical of those prevailing generally in the work of all departments. He notices a certain lack of intensiveness in the work of the colleges, and while admitting that a considerable amount of leisure is wanted for the teaching staff and those engaged in private research, points out that this affords no reason why janitors and gardeners should not carry on their duties out of lecture hours.

On the difficult question of administration, Mr. Cooke expresses fairly definite views. Three methods of administration are possible: firstly, "committee management"; secondly, what he calls the "military type," in which the whole of the direction falls on the shoulders of one man; and thirdly, what Mr. Cooke describes as "functional" management, in which the responsibility is divided amongst a number of individuals, each having complete authority over a limited range of duties. Observing that the system of government by committees does not prevail in the business world, the author objects to this system on the ground that it tends to produce lack of initiative, departmental autonomy, and lack of authority on the part of the heads of departments, especially in the matter of discipline when their decisions are liable to revision at the hands of a board or committee. The functional system is considered to be the best, though the author admits that the other systems are in many cases working well, and better than he would have expected.

Under the heading, "The College Teacher as a Producer," Mr. Cooke refers to the difficulty of increasing the efficiency of professors so long as their duties are so multifarious and varied as they are at present. He is quite astonished at the number of tasks they have to perform. Teaching, research, and administration alone form a group of duties, of which it is difficult for the same individual to combine more than two efficiently. But, in addition, it is becoming increasingly important for the professor to keep himself in touch with what is being done elsewhere, and this involves study of pedagogic methods as well as of the literature of his own subject. Moreover, the committee system, where it exists, makes increasing demands on his time. Yet Mr. Cooke finds professors spending time in taking inventories, keeping track of appropriations, mimeographing examination papers, and handling routine correspondence. "These things," he points out, "are clerical work, and should be handled outside of the teaching field, and not as a part of the teacher's duties." Further on he observes: "The high-priced presidents of our railways, banks, and steel companies would not dream of performing this variety of functions. They would refuse to do so, because they know they could not do them well. This part of raising the efficiency of the college professor will have to be done by building up central agencies for doing much of the work he does now, and for doing it so much better than he possibly can, that he will be glad to relinquish his responsibilities in these respects."

Passing on to the question of "research," the author directs attention to the danger which exists of sacrificing efficiency in other directions, especially in class-teaching, by attaching exaggerated importance to work of a research character. Mr. Cooke is here

[1] "Academic and Industrial Efficiency." A Report to the Carnegie Foundation for the Advancement of Teaching. By M. L. Cooke. Pp. vii+134. (New York City, 1910.)

opening up a question which it will be difficult to discuss adequately without raising controversies of a somewhat heated character, and it is clear that unless the subject be approached with the greatest caution by unprejudiced individuals, an inquiry may do harm instead of doing good. On one aspect of the question little difference of opinion will probably exist. Mr. Cooke directs attention to the case of a professor who felt that his ability lay in the direction of teaching, but who was more or less forced to undertake research owing to pressure from his colleagues. Another authority informed him that it was becoming increasingly difficult to discover profitable lines of research. To those whose main difficulty is to know what can be left uninvestigated and unpublished with the least sacrifice, these remarks must come as a surprise. They may suggest that facilities for research are not bringing relief in the quarters where it is most needed, and that there is something in Mr. Cooke's opinion that research ought to be subject to some kind of control or inspection. But would not such a system, if carried out under existing and not under ideal conditions, have the exactly opposite effect to that which Mr. Cooke desires? The difficulty is that nobody who is not engaged on a piece of original work or research can appreciate its significance and difficulty, and any attempt to assess such work from without would tend to the adoption of a standard of quantity rather than of quality; a premium would be placed on those investigations which were of the most superficial character. In this connection no analogy probably exists in business matters.

Tables are given showing, still for the department of physics, the relative cost and direct expense attributable to research and teaching. For the eight institutions under investigation, research absorbs on the average about one-third of the whole, but the author admits that physics is exceptional. Coming next to the question of economical use of buildings, attention is directed to the small number of hours in which each lecture-room is generally in use, and in this connection the earmarking of lecture-rooms for the exclusive use of one department is deprecated.

The next part of the report deals mainly with proposals for reorganising the administrative side of a college and for better control of its finances. Under the heading of "Functional Activities," the author suggests the establishment or reorganisation of the offices described under the following heads: Superintendent of grounds and buildings; interdepartmental janitor service; purchasing department; stores department; mail handling by a central office; bursar's department; disciplinarian; bureau of publicity; registrar; and bureau of inspection. Under the last heading it is suggested that perhaps the examination system may be found to exercise a useful function, and Mr. Cooke advocates the reintroduction of external examiners for the purpose. Under "Financial Administration" he advocates closer relations between the expenditure on different departments and their corresponding output of work. In a section headed "Physics Departmental Administration" he directs attention to the frequent expenditure of large sums on the purchase of apparatus which are only used for a limited period, and suggests that means should be devised whereby apparatus which have ceased to be useful in one particular college might be made available elsewhere. Under "Student Administration" he instances a few cases of slackness in respect of attendance; this is, of course, a matter that can be easily remedied from within. The rest of the report consists mainly of tables.

The author found everywhere the greatest willingness to cooperate with him in his inquiry, coupled by a keen desire to profit by any suggestions to which that inquiry might lead. No higher praise from a business man to a college professor could be given than his statement: "It would probably be impossible to find a group of men more willing to let one know the full measure of their ideals and of the work done than are the men of the universities." It is clear that if, and so far as, the American universities admit of reforms on the lines suggested, such reforms can and doubtless will be effected from within.

In an English review one is naturally somewhat concerned with the possible effects of Mr. Cooke's report on our own university system, and one cannot but feel a certain apprehension lest such a report falling into the hands of an outsider might be used as a tool for attempting to effect changes from without in a way which certainly would involve a very far-reaching temporary, if not permanent, waste of efficiency.

Now in most of our modern universities and colleges the supreme authority is vested in a council or board of governors consisting mainly of business men, and such a board possesses all the powers of inspection which Mr. Cooke desires to obtain in America. It also, in general, possesses the right of appointing and dismissing any member of the teaching staff, and the safeguards for securing that a professor shall only hold office as long as he continues to prove an efficient teacher are provided for to an extent which probably represents more than Mr. Cooke would consider desirable in his country. The teachers are often called on to furnish such boards with statements as to the progress of work in their departments, and may be called upon to reply to inquiries. In colleges receiving Treasury grants, further inspection on behalf of the Government is also contemplated, and detailed reports have to be furnished as to the work of the colleges and their departments. These reports include statements regarding research and the publication of original work. In regard to the keeping of students' records, different practices necessarily exist in different institutions, but this form of supervision is probably almost universal, and it is certain that in many instances we have got far more than Mr. Cooke would ask for in America.

In regard to the relative expenditure on teaching and research, it is certain that even in a department like physics we cannot furnish figures at all comparing with Mr. Cooke's. A not infrequent experience over here is to find teachers spending a not inconsiderable portion of their small salaries in the purchase of materials for researches conducted in the college laboratories. As regards the apportionment of grants in relation to the work of the departments, we here are usually in the position of having to make a little money go a long way, and the adoption of a standard based on numbers of students has certainly been carried beyond the limit conducive to the greatest efficiency. Last, but not least, there is probably not a college in this country which dispenses with the external examiner or the external examination.

The general conclusion is that the direction in which Mr. Cooke suggests reform tends rather towards assimilating the American university system to the system of most recent development in Great Britain. At the same time it does not necessarily follow that we ought to relax our efforts to move towards the existing American ideal. It may easily happen that the conditions for maximum efficiency are satisfied by some system which is intermediate between the two. While these remarks apply more particularly to such questions as inspection and relative importance of research, it cannot be denied that in the matter of general organisation much the same diversity prevails as Mr. Cooke finds in the United States. At

one centre the committee system is brought to bear on the most trivial details of domestic management; in another case a central authority practically decides even such matters as forfeiture of scholarships in cases of discipline. It may be that these divergences are the result of varying local conditions, but a study of them might well be extended to our universities.

Since the preceding notice was written, we have received a criticism of Mr. Cooke's report by President R. C. Maclaurin, of the Massachussets Institute of Technology, published in *Science*, xxxiii., 838, pp. 101–103 (January 20). Attention is particularly directed to the fact that most of the points raised in the report are not new. "It is full of commonplaces, and there is scarcely a question raised that has not been discussed *ad nauseam* by college professors and other officers. It is not lacking in confidence. One marvels at the temerity even of an 'efficiency engineer' who can lay down the law so definitely as to how to teach physics, how to conduct a recitation, how to carry on research, when most of us who have devoted our whole lives to such problems are far less confident." President Maclaurin specially condemns the "student-hour" standard of efficiency and the proposal for inspection of research, the futility of which has been pointed out above, and he instances his point by the following imaginary dialogue between Newton and the "superintendent of buildings and grounds, or other competent authority."

"*Superintendent:* Your theory of gravitation is hanging fire unduly. The director insists on a finished report, filed in his office, by 9 a.m. Monday next, typewritten, and the main points underlined. Also a careful estimate of the cost of the research per student-hour.

"*Newton:* But there is one difficulty that has been puzzling me for fourteen years, and I am not quite . . .

"*Superintendent* (with snap and vigour): Guess you had better overcome that difficulty by Monday morning or quit."

G. H. BRYAN.

THE MOTIONS OF THE PLANETS JUPITER AND SATURN.

THE January number of the *South African Journal of Science* contains an excellent paper by Mr. R. T. A. Innes on Le Verrier's theory of the motion of the planets Jupiter and Saturn. The title scarcely covers all that is in the paper, for the author concludes with numerical calculations, based upon formulæ developed by himself in the Monthly Notices for 1909, which must constitute a considerable step towards a revision of Le Verrier's theory.

Mr. Innes's chief criticism on Le Verrier is that he has taken 9·7367408 instead of 9·7365514 for the log ratio of the mean distances of Jupiter and Saturn, an error approximately of one part in two thousand.

The error is, however, considerably magnified when its effects upon the series representing the reciprocal of the distance between Jupiter and Saturn are considered, and the author's final conclusion is that the fourth significant figure always, and the third often, is incorrect in Le Verrier's perturbations. The error arose because Le Verrier used the mean distances corresponding in elliptic theory with the mean motions and neglected the systematic effects of the perturbations. Jupiter, for instance, on a distant planet like Neptune, may be approximately considered as coalescing with the sun, making that body heavier by one-thousandth part, and consequently the mean distance of Neptune greater by one part in three thousand.

The mean distance of Saturn needs correction by a greater fraction, nearly one part in two thousand; for when Jupiter is between Saturn and the sun, its attraction amounts to about four parts in a thousand of that of the sun, and the average is thus raised.

Le Verrier's omission is unimportant in all other cases. For the four inner planets the perturbations are so small that the third significant figure is insensible, and for Neptune and Uranus the increment due to Jupiter is practically the same and the ratio inappreciably altered.

We quote, for ready reference, a most valuable table:—

Planet	Log mean distance	
	Elliptic theory	Actual
Mercury	9·5878 2168	9·5878 2160
Venus	9·8593 3781	9·8593 3745
Earth	0·0000 0001	0·0000 0012
Mars	0·1828 9703	0·1828 9616
Jupiter	0·7162 3747	0·7162 3339
Saturn	0·9794 9655	0·9796 7915
Uranus	1·2829 0024	1·2830 9713
Neptune	1·4779 4661	1·4781 4316

Some *obiter dicta* in the paper are of great interest. Here is one:—

"So far as merely obtaining an ephemeris goes, it is probable that the method of special perturbations would have given one for 300 years or so with less labour than was involved in either the theories of Hill or Le Verrier."

This sets one thinking why we want the theories. Of course, we want the general results of theory, the first and foremost being that the mean distances are subject to no secular changes. And we want the outline of the theory of long-period inequalities with rough estimates of the numerical coefficients. But an ephemeris of Neptune could be obtained by special perturbations at 512-day intervals (using a power of 2); fifty intervals of 512 days each would cover the period from its discovery to the present day—a month's work.

It is beginning to be recognised that the "theory, good for ages, in which *t* alone has to be substituted," is incomplete. Le Verrier gave some results for the earth 100,000 years ago, based on his theory. If similar theories existed for the minor planets, we doubt, if we should see Eros falling within the orbit of Mars, the Trojan group being captured by Jupiter, and the zone corresponding to a mean motion double that of Jupiter being cleared of small planets. Possibly these phenomena are due to the secular effects of small causes not at present taken into account. We want, therefore, in the cheapest possible way, to multiply accurate ephemerides for comparison with observation.

THE ANTON DOHRN MEMORIAL FUND.

THE zoological station at Naples occupies a unique position among the biological institutions of the world. It is not only the oldest, the largest, and the best equipped of the biological stations, but it has maintained throughout its existence its thoroughly international character. The founder of this important institution, Dr. Anton Dohrn, died on September 26, 1909, and at the eighth International Zoological Congress, held at Graz during August, 1910, it was decided to raise a fund for an international memorial to commemorate his great achievement.

In case some doubt may be entertained as to the maintenance of the international character of the institution which is now under the management of Prof. Reinhard Dohrn, one of the sons of the distinguished founder, it may be remarked that Prof. von

Graff, the president of the congress, has ascertained that no guarantee has been given for the maintenance of the station by any Government or academy, and that, by the terms of an agreement with the city of Naples, no special rights can be obtained in it by any such body during the period of agreement. Prof. Reinhard Dohrn has assumed the entire responsibility of continuing the work of the station, with the provision that, in the event of his death, the responsibility shall pass to another member of the Dohrn family, and subject to the understanding that the station shall remain a completely international institution, in the benefits of which all countries have the right of participating.

The memorial is to take the form of a portrait in bas-relief, to be placed in the zoological station, and of a fund for promoting the efficiency of the station as an international institution for carrying on research in biology.

The amount collected will be reported in 1913 to the ninth International Congress, which will be asked to formulate the conditions under which the fund shall be handed over to the zoological station. The biologists resident in this country who had signified their sympathy with the proposal to establish the memorial fund, and whose names appear in the international list submitted to the Graz meeting, were invited to attend a meeting which was held in the Natural History Museum, Cromwell Road, S.W., on February 3. As a result of this meeting a number of zoologists, representing the principal centres of research in the British Islands, have been asked to form a sub-committee for the British Empire, in order to assist in the work of the international committee, and of this subcommittee Dr. Sidney F. Harmer, F.R.S., was appointed chairman.

Contributions varying in amount from 5*l*. 5*s*. to 10*s*. 6*d*. have already been paid or promised, and it is hoped that the result of the appeal for subscriptions which is being issued will show that Anton Dohrn's great achievement, the establishment and management of the Stazione Zoologica at Naples, is as fully appreciated here as it is in other parts of the world.

Additional subscriptions may be paid to Prof. S. J. Hickson, F.R.S., of the University of Manchester, who is acting as secretary and treasurer of the British subcommittee. Prof. Hickson will be glad to send a copy of the circular which has been issued to any subscriber whose name has been accidentally omitted in drawing up the list of addresses.

NOTES.

WE are asked to state that the annual meeting of the British Science Guild, to be held on Friday, April 7, at the Mansion House, will be opened at 5.0 p.m. instead of 4.0 p.m., as previously announced. The speakers will be:—The Lord Mayor, Viscount Haldane, Sir William White, K.C.B., F.R.S., Sir Albert Spicer, Prof. J. Perry, F.R.S., Dr. R. T. Glazebrook, C.B., F.R.S., Prof. A. D. Waller, F.R.S., and Sir Philip Magnus, M.P.

THE Bakerian lecture of the Royal Society will be delivered by the Hon. R. J. Strutt, F.R.S., on Thursday next, April 6, on the subject of "A Chemically Active Modification of Nitrogen produced by the Electric Discharge." The lecture will be illustrated by experiments.

AT the anniversary meeting of the Royal Irish Academy on March 16 the following were elected honorary members in the section of science:—Hendrik Antoon Lorentz, Berlin; Max Planck, Berlin; Right Hon. Sir Henry Enfield Roscoe, London; and Charles Sprague Sargent, Cambridge, Mass., U.S.A.

THE proposal to establish a museum for London comes at a moment when the subject is better understood than at any other time. Museum work has taken its place in educational requirements, and local history has been shown to be of supreme importance in the development of good citizenship. Of all localities, London is the outstanding city in Britain possessing a history of unique importance. The site of London has been occupied by man since Palæolithic times, through Neolithic times to the historic period when, as a Celtic stronghold, it first became the settlement of a community. As a Roman city, it possesses the finest remains of Roman antiquities in all Britain. Anglo-Saxon, Danish, and later periods are represented by fine series of objects. Remains of beautiful Tudor architecture have been excavated and preserved by the London County Council, which has also preserved and stored every object of interest discovered during its numerous works; the City Corporation has assiduously collected for many years objects discovered in the city, and there are many local collections of considerable interest, both public and private. All this means that there exists already the materials for a London museum from prehistoric to modern times, and it is matter for intense gratification that Mr. Harcourt, when First Commissioner of Works, should have set his hand to this great project and should have carried it through with the aid of a munificent private benefactor. That London should have its own museum of material history as well as its published records is all to the good, though it is late in the day. It is fortunate that the delay in the accomplishment is accompanied by a goodly storehouse of objects awaiting exhibition in a properly organised museum.

LORD CURZON OF KEDLESTON has consented to allow himself to be nominated by the council of the Royal Geographical Society as president of the society in succession to Major Leonard Darwin, who will retire at the anniversary meeting on May 22, after occupying the presidential chair for three years. The annual dinner of the society will be held this year in the Great Hall of the Hotel Cecil on May 26.

A REUTER message from Paris on March 25 states that M. Sommer, the aviator, has made a flight at Mouzon in a biplane with twelve passengers on board, the total weight being 1439 lb.

BY direction of the London County Council, a tablet has been affixed to No. 32 Soho Square (the National Hospital for Diseases of the Heart), where for many years lived Sir Joseph Banks, who for forty-one years—from 1778 to 1820—was president of the Royal Society.

THE meetings of the Institution of Naval Architects will be held at the Royal Society of Arts on April 5–7. In consequence of the death of the late president of the institution, Earl Cawdor, the annual dinner will not be held this year. On April 5 the presentation of the institution premium to Mr. T. B. Abell will be made.

A BRASS tablet to the memory of the late Mr. Cox has been placed in the Hackney Town Hall. The tablet, which was provided by residents in Hackney, bears the words:—"In honour of Harry William Charles Cox, consulting electrician, who died at Hackney July 9, 1910. He contracted a malignant disease while perfecting apparatus for adapting the X-rays to the relief of human suffering."

THE Bessemer gold medal of the Iron and Steel Institute will this year be awarded to Prof. Henri Le Chatelier, the eminent French metallurgist, in recognition of his

great services in the advancement of metallurgical science. The presentation will be made by the Duke of Devonshire, president of the institute, at the annual general meeting to be held in London in May. The Andrew Carnegie gold medal for 1910 will also be awarded at the same meeting, the recipient being M. Felix Robin, Paris.

THE death is announced of Prof. Kekule von Stradonitz, the Berlin archæologist. He was born at Darmstadt in 1839, and took his degree at Berlin in 1861. He then travelled for several years in the Mediterranean, studying Greek and Greco-Roman antiquities. In some monographs on the Theseion in Athens, and on one of the groups in the Villa Ludovisi, he first developed his methods of research. Early in the 'seventies of last century he was appointed to a professorship at Bonn University, and while here he published two important works, one on Tanagra figures and the other on ancient terra-cottas. In 1887 he was appointed director of the sculptures in the Royal Museums, and later to the professorship of classical archæology, and he held both posts until his death.

A PAPER was read before the Society of Antiquaries on March 23 by Messrs. H. E. Balch and D. R. Troup on the exploration of a late Celtic and Romano-British cave-dwelling at Wookey Hole, Somerset. This is close to the Hyæna Den, explored by Prof. Boyd Dawkins fifty years ago. Beneath a small accumulation of surface material was the Roman deposit, containing coins ranging from Vespasian to Valentinian II. Below this, relics of the domestic life of the cave-dwellers were unearthed—a silver earring with the left frontal bone of a girl, and a large series of iron articles. Charred grain and pulse, together with burnt acorns, throw light upon the limited agriculture of the period. The human remains present a problem, and it is practically certain that the persistent occurrence of these along with waste food-bones indicates cannibalism. The excavations are in progress, and will, it may be hoped, throw further light upon these interesting discoveries.

NATURALISTS throughout the world have an opportunity of showing their appreciation of the labours, and regard for the personality, of the late Dr. Anton Dohrn, by contributing to the international memorial fund referred to elsewhere in this issue. It is proposed to place a portrait of Dohrn in bas relief in the Zoological Station which he founded at Naples, and to establish a fund which will ensure the continued efficiency of the station as an international laboratory of biological research. No memorial to Dohrn could have more worthy or appropriate objects, and we hope that naturalists in the British Empire will give a ready and generous response to the subcommittee's appeal for contributions to it. Subscriptions may be sent to Prof. S. J. Hickson, F.R.S., University of Manchester.

THE report of the advisory committee for the Tropical Diseases Research Fund for 1910 has recently been issued, and contains matter of considerable interest. The fund administered in 1910 amounted to 3245*l.*, and is derived from contributions by the Imperial Government, the Government of India, and various Dominion and Colonial Governments, and is expended on grants to the London and Liverpool Schools of Tropical Medicine, and the Universities of London and Cambridge. Reports are included on the work being done and on the manner in which the grants have been expended. Dr. Wenyon records observations on a malady, "Oriental sore," in Bagdad, and some evidence is adduced that the disease is conveyed by a mosquito, a Stegomyia, sp. Dr. Castellani, of Colombo, records cases of bronchitis in Ceylon caused by an Oidium fungus.

THE seventh International Congress against Tuberculosis is to be held in Rome on September 24–30 next. The English section is being organised by the National Association for the Prevention of Consumption and other Forms of Tuberculosis, 20 Hanover Square, W. All the universities and principal towns in the United Kingdom have been invited to send delegates. An executive committee has been formed for the purpose of arousing interest in the congress in this country, and for collecting suitable material in connection with the subject. Dr. J. J. Perkins will act as honorary secretary of this committee. A representative national committee has also been formed, and many distinguished persons have joined it. The congress next September will be divided into three principal sections to deal with the following subjects:—(*a*) etiology and epidemiology of tuberculosis; (*b*) pathology and therapeutics (medical and surgical) of tuberculosis; (*c*) social defence against tuberculosis.

THE sixty-fourth annual meeting of the Palæontographical Society was held in the Geological Society's rooms at Burlington House on March 24, Dr. Henry Woodward, F.R.S., president, in the chair. The annual report referred to the approaching completion of the monographs of Carboniferous Palæoniscid Fishes, English Chalk Fishes, Cretaceous Lamellibranchs, and British Graptolites. The volume for the year included not only instalments of these works, but also a small, complete monograph of British Carboniferous Arachnida, by Mr. R. I. Pocock. Small monographs of special groups of fossils appeared to be acceptable to the members. The Carnegie Trust for the Universities of Scotland had given to the society the plates illustrating the Carboniferous Palæoniscidæ described by Dr. Traquair. Mr. H. Dewey, Mr. Upfield Green, Dr. A. W. Rowe, and Dr. A. Strahan were elected new members of council. Dr. Henry Woodward was re-elected president, and Dr. G. J. Hinde and Dr. A. S. Woodward were re-elected treasurer and secretary respectively.

WE have received a copy of the third edition of the little book on the Brent Valley Bird Sanctuary, by Mr. Wilfred Mark Webb, the chairman of the Sanctuary Committee and honorary secretary of the Selborne Society. It contains a very fully illustrated account of what has been done in an enclosure of nineteen acres which comes into the London postal district, and those who wish to induce the feathered visitors to their gardens to stay and nest as the spring comes on may obtain from it a number of hints. The price of the book is 7*d.* post free (or in paper boards 1*s.* 1*d.*), and it can be obtained from the secretary of the Selborne Society at 42 Bloomsbury Square. The whole of the sixpence or shilling received goes towards the upkeep of the sanctuary.

MR. T. SHEPPARD, curator of the Hull Museum, in his last quarterly report announces the discovery of a series of Neolithic workshops near Bridlington, the scene of the fabrications of the notorious "Flint Jack," which were suggested by the importance of earlier discoveries in this neighbourhood. The material used by these prehistoric craftsmen was chiefly the black flint found in boulders occurring in the glacial clays and gravels ultimately derived from the bed of the North Sea or from its eastern coasts. Mr. Sheppard has now found a vast number of cores, spoilt flakes or "wasters," and flint-knives under the Bridlington cliffs. One worker seems to have made

a speciality of the pink flints, and some specimens resembling the "pygmy" type have been recognised. The finds now announced include oval or pear-shaped scrapers, a second type possibly used for straightening arrow and spear shafts, and a curved implement, which is believed to have been used as a sickle. These implements are now ready for examination by archæologists in the Hull Museum.

In vol. ii., part iii., of Records of the Albany Museum, Mr. J. Hewitt gives a descriptive account of the South African Batrachia, with supplemental notes on the distribution of the various species.

The American Naturalist for March contains two articles on the "genotype" theory of heredity, the one, by Prof. W. Johannsen, dealing with the conception as a whole, while the second, by Prof. E. M. East, treats the hypothesis in connection with hybridisation. After stating that the genotype theory may prove insufficient, or even erroneous, the former author observes that heredity may be defined as the presence of identical genes in ancestors and descendants, or, as Mageen says, in full accordance with this definition:—"The word heredity stands for those properties of the germ-cells that find their expression in the developing and developed organism."

To the *Verhandlungen schweiz. naturfor. Gesellschaft* for 1910 Dr. F. Sarasin contributes a note on the fauna of the Galapagos Islands, in which particular attention is directed to the flightless cormorant, *Nannopterum harrisi*, and the penguin, *Spheniscus mendiculus*; the latter, which is by far the most northern member of its kind, being regarded as a relict of a former extension of the southern ice. The author supports Baur's view as to the continental origin of the Galapagos group, and suggests that its union with the mainland lasted until North and South America were themselves connected by land, but at a period when there was a temporary sundering by means of an arm of the sea, thereby permitting the influx into the Galapagos area of forms from the Carribean coast and the Antilles.

To Mr. J. D. Hamlyn, the well-known animal importer, we are indebted for a copy of a circular containing reference to additional reports in regard to the African "water-elephant." When in French Congo, in 1905, Mr. Hamlyn came across a Panguin hunter who gave an account of a large water-animal inhabiting a lake in the Fernan Faz (Fernand Vaz) district, unvisited by any white man, and not far distant from the coast. It was described as intermediate in size between a hippopotamus and an elephant, with a thick, hairy hide, but no tusks. These animals spend most of their time in the water, and can stay beneath the surface for considerable periods; they are dangerous to approach, and are never hunted by the natives. It may be added that rumours are current of an apparently similar animal inhabiting lakes in northern Rhodesia, and known to Europeans as "water-rhinoceroses," and that in the first edition of the "Encyclopædia of Sport" Colonel F. T. Pollok, in the article Tapir, stated that he had actually seen one or two of these animals below the Congo, and referred to mention of them in 1894 by Captain H. Bailey in "Travel and Adventures in the Congo Free State."

To the *Verhandlungen schweiz. naturfor. Gesellschaft* for 1910, vol. i., Dr. H. Stehlin contributes observations on the evolution and dental development of various ungulates from the lower Tertiary *Bohnerz* of Switzerland. As we proceed from the lower to the higher stages of this formation, a progressive increase in the size of the different species of various groups, accompanied by an increasing dental specialisation, is very noticeable. *Dichodon ruetimeyeri*, for instance, passes, as regards size, through *cartieri* into *subtilis*, with a gradual increase in the length of the crowns of the first three premolars, and the conversion of the fourth of that series from a triangular into a quadricolumnar tooth; and a progression in the matter of general size and the complexity of the fourth upper premolar is observed in species of the genera Lophiotherium and Palæotherium. In the concluding portion of the paper the author points out that there is evidence of free communication between the Old World and North America during the early Eocene, after which there was a sundering of the two continents, while union was once more resumed in the Oligocene. Africa during the Eocene seems to have had no direct communication with Europe, the relationship between the European early Tertiary lemuroids and the modern lemurs of Africa being capable of explanation by means of a land-connection by way of Asia.

The February number of *The Quarterly Journal of Microscopical Science* (vol. lvi., part ii.) consists chiefly of a long memoir, by Prof. F. H. Edgeworth, on the morphology of the cranial muscles in some vertebrates. In this paper Prof. Edgeworth discusses the very difficult and intricate problem of the segmentation of the vertebrate head. He points out that the probable phylogenetic relationships of the various vertebrate groups are determined by the total morphological evidence available, and that the cranial muscles form one item only of such evidence. The interpretation of this evidence is, moreover, rendered very difficult by secondary modifications which have arisen during phylogeny, such as secondary innervation, convergent evolution and degeneration, and in arriving at any conclusion it is necessary to take into account the development as well as the adult structure. The conclusion at which the author actually arrives is that the morphology of the cranial muscles is in favour of an amphibian ancestry of mammals. This result, however, is only reached by considering the sauropsidan features of the cranial muscles as secondary phenomena, and it appears to us that it can hardly be reconciled with the evidence derived from other embryological characters, and, above all, from the geological record.

In describing a collection of Tertiary insects from the lacustrine deposits of British Columbia, in the second volume of Contributions to Canadian Palæontology, Mr. Anton Handlirsch directs attention to the prevalence of certain groups of flies, especially those of the bibionid section, which appear to have formed the chief element in the insect fauna. These are represented exclusively by the genus Penthetria, which at the present day includes, throughout the world, scarcely more species than those in the collection forming the subject of the paper. While the number of fossil Canadian species is estimated at about thirty-five, the existing forms of Penthetria are thirty-six, the allied genus Bibio including ninety-five. "The occurrence of so disproportionately large a number of penthetrias in the Tertiary of British Columbia contemporaneously with the absence of Bibio indicates that the beds in question belong to the early Tertiary, and are at least Oligocene in age. The supposition is obvious that the genus Bibio originated in the East, probably in Europe, and later found its way into North America." It is added that the occurrence of Penthetria and certain other genera indicates that British Columbia enjoyed a warm climate in the Oligocene.

SOME interesting abnormalities in the flowers of Œnothera are recorded by Dr. R. R. Gates in the twentieth report of the Missouri Botanical Garden. The transformation of the sepals into green leaf-like organs, known as virescence or frondescence, and general modification of the floral organs, appeared in several species, notably in *Œnothera multiflora*. Polymery, or an increase in the number of parts, was manifested in certain hybrids of *O. Lamarckiana*; a curious feature was the occurrence of trimerous flowers side by side with a tetramerous and a heptamerous flower. In some cases there were evident signs of coalescence of two flowers, or synanthy.

NATURAL cross-fertilisation among plants in India forms the subject of the latest botanical issue (vol. iii., No. 6) of the Memoirs of the Department of Agriculture in India, compiled by Mr. and Mrs. A. Howard and Mr. A. Rahman Khan. It is noted that natural crossing among wheat plants, which is very rare in England, but is somewhat more frequent in the drier climates of Europe and North America, becomes more common under the much drier conditions prevailing at Lyallpur. The conclusion follows that wheat breeding in the canal colonies of the Punjab will necessitate the exercise of special precautions. Among the various observations recorded as examples of variation due to natural crossing are colour variations in *Lathyrus sativus*, change of form in tobacco plants, and petal modifications in the opium poppy.

ABOUT four years ago a first catalogue of fifteen pieces of apparatus designed by Prof. W. F. Ganong to serve as instruments for precise measurements in vegetable physiology was issued by the Bausch and Lomb Optical Co., Thavies Inn, Holborn Circus. Those instruments included demonstration clinostat, portable clamp stand, normal light screen, respirometer, leaf-clasp, and bell-jar support. A short supplement to the former catalogue has recently been published, in which new instruments in the form of two space markers and a demonstration auxograph are described. The more useful space marker for root-growth measurements consists essentially of a wheel fitted with a ribbed rubber rim, the ribs being spaced 2 mm. apart. The auxograph is a continuous recording instrument, in which the adjustment of the connection between the growing organ of the plant and the recording pen and other details are carefully devised.

THE survey of the Philippine Islands has advanced steadily since it was undertaken by the Coast and Geodetic Survey of the United States ten years ago. A considerable length of coast-line has been accurately located by triangulation, and a belt of country along it has been surveyed topographically. The hydrographic survey of the waters between the numerous islands has also been vigorously pushed on, 120 charts having already appeared. A map showing the present state of the work appears in the January number of *The National Geographic Magazine*.

THE first number of the Technical Review of the Venezuelan Ministry of Public Works mainly consists of official decrees and regulations, but a small amount of information relating to the country appears in the form of communications from commissions entrusted with exploration of eastern and western Venezuela. The geographical positions of sixteen places in the district of Lara were astronomically determined, and a few notes on the geology and meteorology are added. Similar data are furnished from the country to the southward, and the meteorological observations taken at the Observatory of Cajigal in 1908 are included.

A SUMMARY of the state of the ice in the Arctic sea during the summer of 1910 has been published by the Danish Meteorological Institute. The White Sea was open early, and in the Barentz Sea also the winter ice broke up in May, though the polar ice remained dense. Round Spitsbergen conditions were severe, but in the Greenland Sea, on the other hand, they were normal, and the coasts of Iceland were almost free from ice, though in April and May it was not far from the north-west of the island. The opinion is expressed that there will probably be much ice this spring in the Barentz Sea and to the south of Spitsbergen, while normal conditions are anticipated in Davis Strait, Baffins Bay, and to the east of Newfoundland.

MR. H. J. MACKINDER, M.P., lectured on Monday, March 27, before the Royal Geographical Society on the subject of "The New Geography, its Aims and Methods," wherein he reviewed the present outlook of the geographer in this country and compared it with that of four-and-twenty years ago, when he last discussed the scope of geography before the society. After stating that the geographer in his maps sees the earth's surface and its form, that he studies its history, and appreciates the influence of this upon man, his distribution, development, and history, the lecturer went on to demonstrate that with such an outlook geography became an independent subject of study, teaching, and research. By means of a few selected instances the influence of the physical character of a district on its human history was shown, and the ineffectiveness of historical study without a clear perception of the physical controls was insisted upon. Education on such comprehensive lines may be trusted to give a width of outlook and a power of visualising the relations of a number of factors which must give added power in any branch of knowledge. Research can find ample scope in investigating the effect of the relations between the various physical and human factors, thus furnishing a firm basis for the generalisations of the geographer; and for those whose interest is directed to special branches of the subject, the critical examination of problems arising in them affords opportunities for every geographer so long as he bears in mind its relation to the subject as a whole, and would not restrict the subject to the limits of that portion in which his interest lies.

THE Transactions of the Geological Society of South Africa include (vol. xiii., 1910, pp. 65–92, Plates ii.–ix.) an interesting paper, by Mr. C. B. Horwood, on the carbon found in the banket of the Rand. Mr. Horwood holds that there is some close connection between the presence of the carbon and that of the gold. He holds that the carbon has been deposited, at least in its present position, by secondary action, and that the carbon was probably introduced as a hydrocarbon. He quotes, with apparent approval, Mr. Coste's view that petroleum has a solfataric volcanic origin. Mr. Horwood holds that the carbon at the Rietfontein Mine is usually an indication of the presence of visible gold, and that "where carbon is present good gold values may confidently be expected." According to his account, it appears that it is only occasionally that carbon can be detected in the pay-reefs, and that it is only on the Rietfontein and the Randfontein Mines on the Rand that sufficient carbon occurs to be a characteristic feature of the banket. Carbon is apparently most abundant in the abandoned Buffelsdoorn Mine, which, however, is at Klerksdorp, and not on the Rand. Mr. Horwood's valuable analyses throw doubt on his view that the carbon has been the precipitant of the gold owing to

the very sparse occurrence of the carbon and the lack of agreement between the amounts of carbon and gold. Thus, according to Mr. Horwood's table of analyses of samples from the West Reef dyke of the North Randfontein Mine (Appendix D, p. 92), one of the three specimens containing the highest percentages of carbon had the smallest weighable quantity of gold, and of the two specimens with the highest percentage of gold one had only a trace of carbon, and the other was one of the lowest in carbon in the whole series. Mr. Horwood bears fresh testimony to the fact that throughout the Rand good values are almost invariably found when pebbles of a pinkish-brown quartzite occur in the banket.

To the *Sitzungsberichte* of the Vienna Academy of Sciences (July, 1910), Dr. W. Schmidt contributes a lengthy investigation on thunderstorms and squalls, rapid rises of barometric pressure. The work is divided into two parts:—(1) the observations and results of sixteen months' records of the variometer at the Central Meteorological Office at Vienna, especially with reference to the cases of rapid rises mostly caused by squalls, &c.; (2) experimental investigations of the incursion of heavier (colder), under lighter (warmer) air, and its effect on the formation of the squalls. The latter subject constitutes the essential part of the whole investigation, and this inflowing of the cold air, the author states, never takes place in the form of a simple wedge, but the front portion has the shape of an uplifted head (illustrated in the diagrams). "This head, with the currents that it causes, is the core of the squalls and thunderstorms. In these we cannot therefore speak of an actual whirl with horizontal axis." He considers that another theory must be substituted for the old one, which would explain all the phenomena in squalls essentially by the motions which, under the influence of gravity, must take place from the juxtaposition of two layers of air at different temperature.

The *Zeitschrift für den physikalischen und chemischen Unterricht* issues from time to time special parts dealing with the method of teaching and the philosophy of science. In a part of 120 pages, which has recently appeared, Dr. H. Lüdtke, of the Modern High School (Real-Gymnasium), Altona, gives details of a course on electrical oscillations and the electromagnetic theory of light suitable for the older pupils in modern high schools. It includes construction of a Tesla transformer, experiments to show the repulsion of a metal disc and other mechanical actions of the currents obtained, together with their thermal, optical, chemical, and physiological effects. The portions of the theory of alternating currents necessary for the study of the theory of light are then introduced, and are followed by experiments on electrical oscillations, their interference, diffraction, and polarisation. The course is well thought out, both theoretically and experimentally, and will commend itself to those high-school teachers in this country who have the time and apparatus necessary for the preparation of a course on the subject, and the pupils capable of benefiting from such a course.

A small portable photometer, known as the "Holophane Lumeter," for determining the luminosity of surfaces, has been constructed by Messrs. R. and J. Beck. It measures 8½ by 2¾ by 2¾ inches, and is divided into two chambers, the first of which contains a small electric lamp run from two storage cells. The light from this chamber, the walls of which are painted white, passes through a small opening into the second chamber, which contains the circular photometer screen. The matt-white surface of the screen is viewed through an eye-piece inserted obliquely into the side of the chamber. The surface the luminosity of which is to be determined is seen through an opening in the centre of the screen, and a corresponding one in the end of the chamber. Two sectors, one notched, the other plain, can be moved over the aperture between the two chambers until the brightness of the outer part of the photometer screen is equal to that of the central part. The luminosity of the surface viewed is read on two scales outside the box, over which two pointers connected with the sectors move. One scale reads up to 0·1 and the other to 1·0 candle foot. By means of dark glass screens interposed in the path of the light coming from the surface tested, the readings may be extended up to 100 candle feet. The instrument is standardised by being made to read 1·0 when directed to a white surface 1 foot away from a standard candle.

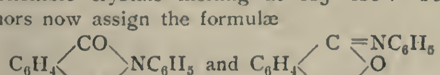
Messrs. Newton and Co., 3 Fleet Street, have just issued a new price-list of X-ray, high-frequency, and electro-medical apparatus. The X-ray apparatus shows evidence of development in several directions. The "Snook" apparatus consists essentially of a step-up transformer immersed in a tank of oil. The primary receives alternating current from a dynamo, which is worked from the electric supply mains. A simple mechanical high-tension commutator is placed in the secondary circuit, and renders the secondary charge unidirectional. The axis of the commutator is continuous with the axis of the dynamo, and thus perfect synchronism must necessarily result. From a convenient switch table the secondary discharge can be regulated from a very small to a very large one. The introduction of this apparatus has led to modifications and improvements in all other forms of generating apparatus; coils have been constructed with a large amount of metal in the core, and a comparatively thickly wound secondary, so as to be capable of giving large discharges comparable with those obtained from the secondary of the "Snook." Mechanical and electrolytic interrupters have also been developed and enlarged in such a way as to enable large primary currents to pass through them.

No marked development has taken place in X-ray tubes in recent years, but there are several on the market now which are able to stand a heavy secondary discharge, and thus enable skiagrams of the thicker parts of the body to be taken with very short exposures. The accessory apparatus described in Messrs. Newton and Co.'s list referred to above includes certain devices for the protection of the operator. One of these is a lead-lined cabinet in which the observer and one or two others can incarcerate themselves while the X-ray tube is in action. The switchboard is placed in the cabinet. A cabinet of this sort was introduced some years ago by Dr. Albers-Schönberg, of Hamburg. Its utility is confined to cases in which X-ray treatment is to be given, or an X-ray photograph is to be taken, though it is obviously of no use for fluorescent-screen observation, a most important part of diagnostic X-ray work. For protecting the operator during fluorescent-screen operations, Dr. Jordan's adjustable lead-lined screen is illustrated, and also the revolving saddle upon which the patient is seated during the use of this lead-lined screen. Several old patterns of tube stand are still figured in which the X-ray tube is not enclosed in a protective shield or box. Thus on p. 69 two naked X-ray tubes are shown supported by a single jointed clamp. No X-ray tube should ever be used in this unprotected state at the present day, and it would have been better to have omitted such stands from the price-list, as they are a source of danger to those who use them.

UNDER the title "Chemische Weltliteratur," Dr. Wilhelm Ostwald communicates an article to the current number of the *Zeitschrift für physikalische Chemie* which raises a question of very general interest. He points out that the convention under which all scientific publications are published in one of the three "great" languages (English, French, or German) shows signs of breaking down. Partly through an increased sense of nationality, partly through the difficulty of writing freely in a foreign tongue, numerous valuable publications are now published in Italian, Spanish, Russian, Polish, and other languages. This tendency renders it difficult, if not impossible, for a worker in any given branch of science to learn what has already been done in his own subject. Dr. Ostwald then discusses the possibility of an agreement on an international speech for scientific publications. Owing to the large number of new conceptions and terms, the use of Latin for this purpose is no longer possible, and *Ido*, an improved and developed Esperanto, is suggested as a solution. A general outline of this artificial language is given, and a nomenclature especially adapted to chemistry is sketched out. The subject is one which might well receive attention at international scientific congresses, and if it were possible to arrive at a general agreement, even in one or two isolated sciences only, a real step in the diffusion of science would be made.

WE have received from the publishers, Gebrüder Borntraeger, of Berlin, the first number of a new magazine entitled *Internationale Zeitschrift für Metallographie*. Although published in Berlin and edited by Dr. Guertler in that city, the new journal aims at an international character, and the list of collaborators includes the names of the leading workers in metallography in this country, as well as in Germany, America, Sweden, and Italy. The journal is intended for the publication of papers in German, English, or French dealing with the whole range of metals and alloys, each paper being accompanied by a brief abstract in all three languages. If the new journal can secure the necessary contributions in such a way as to avoid the wide scattering of metallographic papers which now occurs, it will prove extremely useful. It is, however, recognised that British authors who are accustomed to present their work to scientific or technical societies will not be able to abandon these in favour of the magazine; such papers are therefore either to be reprinted in full or to be fully abstracted. The present number of the journal contains introductory matter by the editor, and two papers of some interest, one by Profs. Heyn and Bauer (Berlin) on internal stresses in cold-wrought metal, and the other by Prof. Mathewson (U.S.A.) on sodium-silver alloys. The experiment of establishing an international journal of this kind is an interesting one; if successful, it may lead to similar developments in other branches of science.

A RECENT issue of the Memoirs of the College of Science and Engineering, Kyoto Imperial University, contains two interesting papers on isomerism of different types. In the first paper, by Prof. Kuhara and Mr. Komatsu, on isomeric phenylphthalimides and some allied compounds, the authors describe a number of pairs of isomeric derivatives of phthalimide. The parent substance is only known in one form, but phenylphthalimide has been obtained in colourless needles melting at 83°–84°, and in yellow rhombic crystals melting at 125°–126°. To these the authors now assign the formulæ



(Colourless) (Coloured)

Similar formulæ are assigned to the colourless and yellow isomeric compounds prepared by the interaction of phthalyl chloride with six substituted anilines, and also to the colourless and yellow *p*-methoxy- and *p*-ethoxy-phenylphthalimides prepared some years ago by Piutti and Abati. The isomeric compounds yield identical derivatives when acted upon by the Grignard agent. The second paper, by Prof. Kuhara and Mr. Todo, deals with the Beckmann rearrangement. The authors conclude that the interchange of radicles which takes place, *e.g.*, by the action of benzenesulphonic chloride on benzophenoneoxime is due to the dissociation of an acid radicle from the nitrogen atom

$$\begin{array}{c} C_6H_5.C.C_6H_5 \\ \| \\ N.O.SO_2.C_6H_5 \end{array} \rightarrow \begin{array}{c} C_6H_5.C.C_6H_5 \\ \| \\ N\ldots OSO_2C_6H_5 \end{array} \rightarrow$$

$$\begin{array}{c} C_6H_5.C.O.SO_2.C_6H_5 \\ \| \\ N.C_6H_5 \end{array}$$

A compound of the latter type, having the formula

$$\begin{array}{c} C_6H_5.C.O.CO.CH_3 \\ \| \\ N.C_6H_5 \end{array}$$

has actually been prepared as an unstable yellow oil, and has been shown to pass over at once into benzanilide when acted on by hydrochloric acid.

THE new edition—the third—of Prof. Karl Pearson's "Grammar of Science" is to be issued by Messrs. A. and C. Black in two volumes, the expansion of the text having rendered it too large for one volume. There will be an entirely new chapter dealing with birth-rates, race suicide, and degeneracy. The first volume will be published immediately, and the second volume in the autumn of this year.

OUR ASTRONOMICAL COLUMN.

ASTRONOMICAL OCCURRENCES FOR APRIL:—

April 1. 5h. 45m. Venus in conjunction with the Moon (Venus 0° 14′ N.).
9. 7h. Neptune at quadrature to the Sun.
14. 15h. Mercury at greatest elongation east of the Sun (19° 42′ E.).
14. 17h. 6m. Jupiter in conjunction with the Moon (Jupiter 1° 41′ N.).
19. 23h. Uranus at quadrature.
23. 13h. 11m. Mars in conjunction with the Moon (Mars 3° 45′ N.).
24. 20h. Mercury stationary.
28. 10h. 16m. Sun eclipsed, invisible at Greenwich.
28. 14h. 46m. Saturn in conjunction with the Moon (Saturn 2° 17′ S.).
29. 10h. Venus in perihelion.
30. 16h. Jupiter at opposition to the Sun.
30. 18h. Saturn in conjunction with the Sun.

OBSERVATIONS OF THE ZODIACAL LIGHT.—Some interesting observations, illustrated by sketches, of the Zodiacal Light are recorded by Herr Hoffmeister in No. 4484 of the *Astronomische Nachrichten*. The observations were made at Sonneberg, Thüringen, during February and March, 1910, when, it will be remembered, the light was particularly visible during the apparition of comet 1910*a*, which is shown on one of Herr Hoffmeister's sketches (February 3). On this date, at 7h. 10m. (M.E.T.), the summit of the brightest portion of the Light was at $\alpha = 17°$, $\delta = +10°$, and on March 5, at 8h. (M.E.T.), it lay in the position $\alpha = 33{\cdot}5°$, $\delta = +15{\cdot}5°$; Herr Hoffmeister also gives the positions of a number of points marking the northern and southern limits. To provide a scale for the brightness of the various parts of the Light, Herr Hoffmeister selects and names various parts of the Milky Way with which he compared it; this scale, of five steps, should prove useful in making comparisons of the Light from time to time.

THE ADOPTION OF STANDARD TIME IN FRANCE.—To *La Nature* (No. 1970) M. H. Cathenod contributes an interesting illustrated article on the international system of standard time, to which France has now given its support. He outlines the history of its general adoption, the reasons for accepting the Greenwich meridian as the basis of the system, and the reasons for France's hesitation in entering the international agreement earlier. The article is usefully illustrated by a number of sketch-maps, and, in concluding it, M. Cathenod reiterates M. Faye's hope that, in return for the international adoption of the Greenwich meridian as the point of departure, Great Britain will favour the unification of the system of weights and measures by adopting the metrical system.

THE DIFFERENT FORMS OF HALOS AND THEIR OBSERVATION.—Although a large number of famous astronomers and other observers have directed their attention to the halos which are to be seen from time to time surrounding the sun or moon, these phenomena still present some unsolved problems. In the March number of *L'Astronomie* Dr. Besson, of the Montsouris Observatory, suggests that the observations should be made regularly by amateurs, for the phenomena are visible without the help of instruments; but the amateur often lacks the knowledge of what to look for and what is worth recording. To remedy this state of affairs, he gives some excellent descriptions and instructions well illustrated by numerous diagrams.

Two of these diagrams show the solar halo of 22°, the halo of 46°, the upper and lower tangential arcs, the parhelia and anthelia, the oblique arcs and the luminous column and the arcs of Lowitz. Each phenomenon is then described and discussed, so that the observer may know when and where he may expect to see it, and what colours, if any, should attend it. Special notes and a diagram are given for the circumzenithal arcs, which are not so frequently seen, and generally last not longer than five minutes. M. Besson finds that the observations published in late years favour the theory of Bravais as to the appearance of these arcs, a theory which Pernter did not accept. This article is to be followed by another, in which the author will describe some of the rarely seen and abnormal phenomena which attend the apparitions of halos.

NOVA LACERTÆ.—In an article which appears in No. 9, vol. civ., of *The Scientific American*, Prof. S. A. Mitchell gives some very interesting facts concerning the apparition of Nova Lacertæ and the discovery and nature of novæ in general. Since the first recorded nova, that of Hipparchus in the year 134 B.C., only thirty-six new stars have been observed, and of these eighteen have been discovered since 1885; fifteen of these have been first found on photographs, and, of the fifteen, fourteen were discovered at the Harvard College Observatory from plates taken there or at Arequipa.

The photographs of Nova Lacertæ taken by Profs. Barnard and Wolf show that between November 19 and 23, 1910, the light of the star increased 4000-fold. A spectrum secured by Prof. Frost, using the 40-inch refractor at the Yerkes Observatory on January 3, is stated to be exactly analogous to those of Nova Aurigæ and Nova Persei, so that any explanation which accounts for their peculiarities will also explain Nova Lacertæ. Prof. Mitchell discusses, very briefly and generally, the causes which may produce novæ, and shows that the "pressure" theory and the "collision" theory leave much to be explained; he rather favours the passage of a rapidly moving star through a previously unknown nebula. The article is well illustrated, the reproductions including photographs of the Harvard College observatories at Cambridge (Mass.) and at Arequipa.

THE STAR LIST OF THE AMERICAN EPHEMERIS, 1911.—For thirty years (1882–1911) the star list of the American Ephemeris has given ten-day ephemerides for the apparent places of some 378 especially chosen stars, and daily ephemerides for five circumpolar stars. The need of a larger and improved star list for the use of astronomers, engineers, and surveyors prompted the issue, in 1908, of the list of 780 stars for 1909, and the present issue is similar to that except that forty-five more stars have been added. As the Ephemeris for 1912 contains a list identical with the present issue, the publication of a separate Star List will not be continued.

EPHEMERIS FOR WOLF'S COMET.—In No. 4483 of the *Astronomische Nachrichten*, M. Kamensky continues his ephemeris for Wolf's comet, which may return to perihelion in February next. At present the comet is apparently in Aquila, about half-way between δ Aquilæ and η Serpentis, and is moving in a north-easterly direction; its calculated magnitude is about 14.

ANTARCTIC EXPEDITIONS.

THE centre of interest in polar exploration has been shifted, earlier than might have been expected, from the north to the south by the telegram forwarded from Stewart Island from the returning *Terra Nova*. This vessel has carried Captain Scott's expedition to its base successfully in spite of encountering heavy pack-ice in the remarkably low latitude of 65° S., and having to make 380 miles of difficult travelling through it. The telegram includes messages from Captain Scott and from Lieut. Pennell, the officer commanding the *Terra Nova* on her return, and it is in the latter message that the salient point of interest is found, namely, the discovery of the celebrated *Fram*, with Captain Amundsen's expedition aboard, already established in the Bay of Whales, an inlet in the ice-barrier at 165° W. long. It is perhaps early as yet to account for Amundsen's change of plan (for he originally sailed ostensibly with an Arctic journey in view); the interest of the moment is that, assuming his base to be established at the Bay of Whales, he is nearer the Pole by nearly 100 miles than Scott if he elects to strike south in a direct line, and risk discovering a new route up to the polar plateau. If, however, he makes for Shackleton's known route (which Scott, of course, will follow) up the Beardmore glacier, he will have little if any advantage in distance.

Some uncertainty as to Scott's arrangements is caused by the messages. His own states that after leaving him at the base in McMurdo Sound the *Terra Nova* would leave a geological party on Victoria Land, and then proceed to leave an exploring party on King Edward Land. As a fact, it appears that the *Terra Nova* proceeded along the ice-barrier towards King Edward Land first, failed to make a landing at Cape Colbeck, and returned to the Bay of Whales. Here the *Fram* was found, and here two interpretations have been put upon the message:—"The *Fram* is proceeding to Buenos Aires, returning the following season to re-embark Captain Amundsen. Stores were landed and a hut erected two miles from the ship, and the *Terra Nova* afterwards left again for McMurdo Sound."

Some commentators refer the stores and hut to the party from the *Terra Nova*, which seems the more probable on the face of the sentence; others suspect wrong paragraphing, and suppose the stores and hut to belong to Amundsen's party. Later the ship was driven north, and landed the "eastern" party at Cape Adare (Victoria Land), which would suggest that the second group of commentators are right, and leaves it uncertain as to what has become of the geologists. This will doubtless be cleared up when the ship reaches another cable station; in the meantime, it seems reasonable to hope that there will be room in Victoria Land for Scott's party (especially if they are geologists only) and the expedition of Dr. Mawson, who has expressed some doubt as to the inviolability of his province.

Scott, Amundsen, and Mawson (who will have as commander Captain J. K. Davis, late of the *Nimrod*) do not exhaust the list of those already attacking or intending to attack the problems of the south. A Japanese expedition under Lieut. N. Shirase, having little in common with European equipment beyond a characteristic determination, was reported to have left for the south at the end of last year. Nor is it certain that an American expedition has been given up, in spite of Commander Peary's determination not to lead it, for it is stated that his captain, Bartlett, is ready to take his place.

It may be added that already Scott's expedition has added something to scientific knowledge, for those returning on the *Terra Nova* have carried the north coast of Victoria Land (by distant sights) some 150 miles beyond its previously known extension, and the interesting feature of an open sea immediately south of the Balleny Islands was encountered.

THE USE OF RADIO-ACTIVE SUBSTANCES IN THERAPEUTICS.

THE *British Medical Journal* for February 4 contains a report of an address delivered before the Berlin Medical Society on January 18 by Prof. Wilhelm His, of the University of Berlin, on "The Treatment of Gout and Rheumatism by Radium." Prof. His was led to make the investigations upon which the address was founded by the consideration that radium, or at all events some of its derivatives, formed a constituent of certain natural curative springs, the action of which on gout and rheumatism is undoubted, though medical men have not been able to explain it satisfactorily. It soon became evident that both radium and radium emanation were capable of producing cures, which were especially remarkable in the case of gout and of the various rheumatic affections. The results obtained were reported by the lecturer about a year ago to the German Balneological Society. Since then his experience has considerably extended.

The patients dealt with include 100 cases of chronic rheumatism and 28 of uric acid gout. Of the former, 47 were improved, 29 considerably improved, 5 nearly cured, while 19 were uninfluenced by the treatment. The most interesting of the cases were those in which limbs rendered useless by the disease were almost completely restored by the treatment, which was continued for periods of three months or longer. In gout, the results were much more striking. Twenty-eight patients were kept under treatment and under observation for a considerable period. Of these, 4 remained unaffected, while in 24 a marked improvement in the condition was achieved. Some of the patients have remained free from symptoms for a year after the termination of the treatment.

The most remarkable effect is noted in the behaviour of the uric acid in the blood. Under the influence of radium emanation, the blood loses its uric acid within a few weeks. This was observed in 15 cases out of 18. On the other hand, the uric acid persisted in the blood of 3 patients even after a severe course of treatment. On two occasions actual deposits of uric acid under the skin of the ear (so-called "tophi") were seen to disappear during the treatment. The clinical improvement did not always run parallel with the uric acid content of the blood. Thus very marked improvement was obtained in a patient by energetic treatment, though the blood continued to contain uric acid. In another patient no uric acid was present in the blood either at the beginning or the end of the treatment, although he had gouty nodules all over his body.

When water containing radium is drunk, part of the emanation is taken up in the inspired air, and another part is absorbed from the stomach and intestine. Emanation behaves like every other gas which is not a normal constituent of the body. It is excreted to a very slight extent through the kidneys, and to a large extent in the expired air. When the treatment is carried out by baths, absorption is only continued so long as the patient remains in the atmosphere laden with emanation from the bath water, and the foreign gas is excreted immediately. On the other hand, when carried out by means of drinking waters, the absorption takes place slowly from the intestine, and the body is being constantly supplied with fresh doses of emanation for three or four hours after a single dose. When the patient is given from three to five doses during the day, emanation can be detected in the expired air at any period of the day.

Radium itself behaves in the body like other heavy metals; that is to say, it is absorbed slowly, and the absorbed quantity is excreted again through the intestine. So long as it is present in the body, small quantities of emanation are continuously developed from it. It is therefore clear that the most active application of emanation is achieved when the individual is breathing an atmosphere which contains a certain quantity of radium emanation. Under these conditions, an equilibrium will rapidly be established between the emanation content of the outer air and that of the blood. This equilibrium will be maintained so long as the body remains in this atmosphere. The emanation content of the blood will reach a level in this way which can only be attained by the drinking of exceptionally large quantities of water containing radium. Experiments have shown that it is usually sufficient for the purpose of obtaining definite curative results, and of ridding the blood of gouty patients of uric acid, to place the patient in an air containing from two to four "making units" per litre for two hours a day. "Emanators" have been constructed on this principle. A stream of oxygen bubbles through a fluid containing a salt of radium and is saturated with emanation. The emanation issuing from the fluid is distributed equally in the air of the room by a ventilator. This method, however, has the disadvantage that it can only be applied when a special emanator is available. A portable inhalation apparatus has also been constructed.

With regard to the mode of action of radium, the most important factor appears to be the property possessed by radium of rendering various ferments of the body more active than usual. This power of activising ferments has been demonstrated in the case of pancreatin, pepsin, lactic acid ferment, diastatic ferments, and autolytic ferments. It is probable that the same is true of numerous other ferment actions in the body, though not for all; for example, it is known that the excretion of sugar by diabetics is not influenced by radium. In the case of gout, this property of radium can be demonstrated in a very clear manner. The disturbance in gout has been shown to depend on a slowing of the purin body metabolism, and not only is the formation and breaking down of uric acid slowed, but the mutual relations of the two processes are altered. In the gouty this is shown by the fact that, on a diet free from purin, though containing nucleic acid, the uric acid formed is not completely excreted within five days, as is the case in healthy persons. After prolonged treatment with emanation, however, the excretion takes place as promptly and completely as in a healthy individual. Gudzent was further able to show that uric acid and its salts are dissociated into carbon dioxide and ammonia under the influence of this action, and he demonstrated in a very ingenious manner that neither radium nor radium emanation produces this dissociation. It is due to radium D. Thus the actions that come into play in the treatment of gout by radium are very varied. In addition to the autolytic action, the action inhibiting inflammation, and that alleviating pain, there is a specific action on the uric acid and its salts, and on the processes regulating the quantity of uric acid in the body.

Another radio-active substance—mesothorium—has been prepared in considerable quantities by Dr. Otto Hahn. As compared with radium, the want of durability of this preparation is amply compensated by the greater ease with which it can be obtained from raw material. It is more than probable that other radio-active substances will be discovered, and will bring the treatment of gout and allied complaints by radio-active substances within the reach of all. A great deal of experiment and observation is still required, more particularly to make sure that no evil results may appear side by side with the undoubted benefit which has already been obtained.

A. C. JORDAN.

THE AERO AND MOTOR EXHIBITION.

THIS exhibition opened at Olympia on Friday, March 24, and will continue until Saturday, April 1. A general survey of the flying machines shown indicates that the crank inventor is less conspicuous than has been the case at former exhibitions, and that the British makers have achieved notable progress during the past twelve months both as regards design and workmanship. Most of the machines have evidently been designed and constructed with a view to military requirements. Thus among foreign machines is the Breguet three-section military biplane, one of the favourites with the French War Department. This machine is built almost entirely of steel, thus cutting down the number of parts and the amount of wiring. The spars of the wings consist of large diameter steel tubes, to which the ribs are elastically attached, forming a supple surface which is claimed to give almost entire automatic stability. Another French War Department machine is the Nieuport two-seater monoplane, chiefly remarkable for its high speed—63 miles per hour.

Graham-White has a small biplane on show. This machine has a span of 27 feet and an overall length of 32 feet, and is fitted with a Gnome engine of 50 horse-power driving a four-bladed propeller. On account of the small span and chord, the machine is exceptionally fast, and has been repeatedly flown in gusty winds of velocity up to 35 miles per hour. Aluminium has been entirely dispensed with in the construction, the whole of the fittings and connections being of steel. The machine can be separated into three sections for transport.

The British and Colonial Aëroplane Company, Ltd., exhibit three of their now well-known Bristol machines, a military biplane, a racing biplane and a monoplane. The planes in the biplane type are so shaped—from experimental evidence—that a considerable amount of lifting power is in reserve under normal conditions of flight. The Gnome engine is used by this firm, who are the sole agents for it in Great Britain and the Colonies.

The Sanders Aëroplane Co., of Beccles, Suffolk, and London, exhibit a biplane having some novel features. The extreme tips of the upper planes dip downwards, both upper and lower planes being set at a dihedral angle. There is a biplane elevator in front and a triplane rudder at the rear. Balancing planes are placed between the main planes, and no tail plane is fitted. The peculiar shape of the wings is claimed to give great stability, even in high winds. The main frame of this machine has diagonal braces consisting of flat steel strips. The carriage comprises two skids, and is fitted with two wheels which draw up under the body when released by a trip device, enabling the machine to alight on the skids alone. The outer portions of the main planes are hinged to the central portion, and may be folded inwards for convenience in storage and transport.

Among historical machines shown by the Royal Aëro Club is the Blériot monoplane on which Graham White won the Gordon Bennett Cup at Belmont Park in October, 1910; the Howard Wright biplane with which Sopwith won the Baron de Forest prize of 4000*l.* by a flight of 169 miles, from England to Belgium, in 3½ hours; and the Cody biplane, with which Mr. Cody won the British Michelin Cup. The latter is fitted with a Green four-cylinder engine. The Blériot machines shown in another part of the exhibition are fitted with small skids at the rear in place of the single wheel present in last year's machines.

Many well-known types of engines are exhibited, those most generally in evidence being the Gnome and the Green. The Isaacson engine, made at the Boyne Engine Works, Leeds, at first glance might be mistaken for a Gnome. It has seven radial air-cooled cylinders, which, however, do not revolve. The casing enclosing the crank also contains a two to one reducing gear, so that the propeller, which is coaxial with the crank shaft, rotates at half its speed. The development of this engine will be watched with interest.

THE GLANDS OF RUMINANTS.

In the issue of the Zoological Society's Proceedings for December, 1910, Mr. R. I. Pocock makes an important addition to our knowledge of the specialised skin-glands of ruminants. The value of this communication lies in the fact that it is largely based on the examination and dissection of animals from the society's menageries, whereas, with the exception of the observations published years ago by Brian Hodgson, much of our previous information appears to have been gleaned from museum specimens, which are obviously ill-suited for a study of this nature. The most common of these glands occur near or between the base of the front surfaces of the hoofs (pedal), on the carpus or "knee," where they form tufts in numerous antelopes, on the tarsus and metatarsus of many members of the deer-tribe, on the face below the eyes (preorbital), and in the groin (inguinal). After a review of the structure of these glands, their occurrence or absence in various genera, and their taxonomic value, the author discusses, firstly, their function, and, secondly, their origin and evolution.

As regards function, Mr. Pocock is of opinion that the limb-glands and hoof-glands are mainly for the purpose of tainting the grass or ground through or on which the animals have passed, or upon which they have lain, thereby serving to indicate to the members of a species the whereabouts and the reposing-places of their fellows, the inguinal glands of sheep and many antelopes corresponding practically, so far as their function is concerned, to the tarsal and metatarsal glands of deer. The preorbital glands, on the other hand, appear to be connected to a considerable extent with the sexual function, although it is possible that they may likewise help in directing the members of a herd to the line taken by those in advance.

In structure the preorbital glands range from a more or less complexly invaginated sac to simple glandulation of the surface of the skin; and it appears that the knee-glands of gazelles and the tarsal and metatarsal glands of deer are of the latter simple type, the glandular area itself being naked in a few deer. The glands in the groin, on the other hand, seem to be intimately connected with the milk-glands, their secretion in some instances having an odour like that of sour-milk. The interdigital, or hoof, glands take the form of invaginated sacs of varying degrees of complexity, and appear to attain their fullest development in the type of foot characterised by a long cleft between the toes in front and of a web connecting them behind, such as is found in deer, sheep, and many antelopes. Such deeply cleft and highly glandular feet must apparently be a source of weakness to bulky animals which move rapidly on hard ground; and there accordingly seems to be a tendency in such species to strengthen the foot by obliterating the cleft, with the more or less complete loss, not only of the interdigital, but of all limb glands. The culmination of this takes place in cattle, which lack glands both on the limbs and on the face.

Apart from the consolidation of the foot and the loss of the interdigital glands, the total absence of glands in the members of the ox and buffalo group may, the author suggests, be accounted for as follows:—

"Large ruminants," he writes, "are much more easily kept in view by members of their own species than small ones; or, if they live in thick bush, are more easily followed by hearing, as they crash away in a state of panic through the vegetation." It is added, however, that these and kindred subjects cannot be fully or definitely explained in the present state of knowledge. R. L.

SOME NEW SOUTH AFRICAN MARINE ANIMALS.[1]

The volume referred to below contains a report on the material collected during the investigations of the Cape Government, carried out under the direction of Dr. Gilchrist. The larger part of the report is contributed by Prof. R. Bergh in a paper on South African opisthobranchs (with fourteen plates). Prof. Bergh is able to make a large addition to our knowledge of these animals, since only five species have been previously recorded in this region. He describes eight apparently new Aplysias, a Cape Philine, and other new tectibranchs. Many new holohepatic nudibranchs were found, including a second species of Kalinga. Several new cladohepatic nudibranchs are also described, the most interesting of which is placed in a new genus as *Tritonidoxa capensis*. The paper is illustrated by numerous valuable drawings of organs of specific differential value, and there are two coloured plates.

In looking over Bergh's anatomical contributions, one concludes that he must have many valuable drawings of complete systems of organs, as, for example, of the genitalia. There is no doubt that the publication of more of such drawings would be warmly welcomed by students of nudibranch anatomy.

Reviewing the faunas of the coast west and east of the Cape of Good Hope Peninsula, Bergh points out that the former has a more northern character, with occasional tropical nudibranchs, while the latter is more tropical.

Dr. Gilchrist has an interesting contribution on three new forms of hemichordata: a new species of Phoronis, *P. capensis*, the behaviour and habits of which are interestingly and fully described, and a form which differs

[1] "Marine Investigations in South Africa." Vol. v. Pp. 198. From the Transactions of the South African Philosophical Society, vol. xvii. (Cape Town: Published by the Society, 1908.)

from the typical Phoronis in having an involution of the epidermal cells below the œsophageal nerve collar; it has been allotted to a new genus as *Phoronopsis albomaculata*; the third form is a Ptychodera, *P. capensis*, a brief preliminary description of which is given.

In a short paper Miss Lydia Jacubowa describes a new species of Plarocera, *P. gilchristi.*

Dr. Calman contributes an account of a parasitic copepod from *Cephalodiscus gilchristi* from the Cape Seas. An interesting point about this new form is that it is referable to the family Ascidicolidæ as *Zanclopus cephalodisci* (nov. gen. et sp.), and is thus closely allied to forms infesting tunicates. The author points out that as the nearest ally of Zanclopus is a form infesting the echinoderm Antedon, the nature of the parasite in this case does not necessarily have any bearing on the chordate affinities of the host; nevertheless, the point has some value in such discussions.

Mr. F. Gordon Pearcey concludes this volume with a paper on the genus Botellina, with a description of a new species, which is a gigantic arenaceous rhizopod, attaining a height of 1 to 2½ inches.

Vol. vi. of the Marine Investigations will be published in the Annals of the South African Museum.

SOME MODERN METHODS OF ORE-TREATMENT.

AT the twentieth annual general meeting of the Institution of Mining and Metallurgy, held on March 22, the new president, Mr. H. Livingstone Sulman, was inducted into the chair, and delivered an address in which he reviewed some modern methods of ore-treatment. At the outset, attention was directed to the increasing complexity of metallurgical science, and the need for specialisation on the part of those engaged in its practice. Each stage of production for every finished metal demands its own specialised services from the miner, the metallurgist, and the metal worker, and the task of each daily becomes more elaborate in detail.

After paying a passing tribute to the debt owing to the technical chemist and the mechanical engineer, who have enriched metallurgical practice with such a wealth of ingenious and useful apparatus, Mr. Sulman passed on to a general review of the metallurgical industry, its conditions and requirements, incidentally touching on some of the more important processes now in operation in the treatment of various metals. Zinc-fume precipitation of gold solutions, oil-flotation in aiding recovery of gold and tin, electrolytic cyanidation, the use of cyanogen iodide and of bromocyanide, of silica sponge brick and other methods, were briefly noted, and the speaker then dealt with the rapid development that has recently come about in the treatment of "complex" ores, in which blende, more or less ferruginous in character, is in intimate physical association with galena and other minerals. The means by which such ores can be attacked may be divided into two broad classes, proximate or mechanical methods, and ultimate or leaching and smelting processes. Among the former, flotation methods (somewhat indiscriminately termed "oil" and "surface tension" processes) are now largely used, though there is still apparently much to be learned in this department, especially with regard to the underlying physical reactions, and the need for a practical solution of the slime problem. Magnetic separation, electrostatic methods, and centrifugal machines are also among the mechanical devices which are still in vogue. In processes dependent on the prior removal of zinc by distillation, comparatively little progress has been made; but the reproach often levelled against zinc metallurgists of being behindhand and incomplete in their practice is unmerited, since the conditions surrounding the reduction of zinc oxide to metal are peculiar, and the reactions involved are so highly endothermic. A feature of the zinc industry is its limitation to comparatively few smelting centres, a localisation due primarily to the necessity for cheap fuel, the occurrence of the peculiar clays required for retorts, and climatic conditions. Ultimate methods of treating complex ores introduce a variety of processes devised to meet diverse circumstances, and include leaching processes, electrolysis, electric smelting, and other means.

Mr. Sulman also touched on the treatment of copper ores, and in this connection led up to the necessity for the conservation of what the present generation is too apt to regard as "waste" tailings, but which in the future, with more advanced methods, may prove to be sources of considerable profit. This question of profit, present or ultimate, should, of course, be the dominating idea in all metallurgical work, for, as pointed out earlier in the address, whilst the labours of the chemist, the physicist, the engineer, the mechanician, and the electrician are all important in their respective spheres, the accountant must in effect dominate all.

THE ORGANISATION OF TECHNICAL EDUCATION.

AN open meeting of the London Branch of the Association of Teachers in Technical Institutions was held on March 25 at the South-Western Polytechnic. The chairman of the branch, Mr. J. Paley Yorke, presided, and Dr. R. T. Glazebrook, F.R.S., opened a conference on the organisation of technical instruction, especially in connection with the higher branches. Dr. Glazebrook's address was confined mainly to the question of the organisation of some form of technical university in London. As a keynote he quoted, from his recent speech at the Guildhall, three main points to the effect that (*a*) an independent faculty of technology in London University had become a necessity; (*b*) definite value should be given to the technical instruction in each London school of technology; (*c*) the technical faculty should have power to confer degrees under conditions which should be laid down by the faculty. He pointed out the difficulties which lay in the way of establishing an independent university of technology, and affirmed that these need not exist if separate and independent faculties were established in the existing university. Moreover, each faculty could be treated as if it were a university. It could have its own active body of control composed of representative business and professional men of wide views and sound knowledge of and interest in local necessities and conditions. This body would be similar to the controlling bodies of such provincial universities as Birmingham or Leeds. It could have its council to keep in touch with the governing bodies of the various institutions in the faculty, to approve the various courses of instruction, and adjust the degree of "recognition" of the work done in each institution. This council should consist of representatives of employers, employees, and teachers. It could also have its board of studies, composed of teachers of various subjects under the faculty, to arrange the educational courses and examinations. These independent faculties would have to be connected in some way to prevent overlapping. This could be done by means of advisory committees which should advise a board of trustees, which would see that the freedom of the faculties was not abused, adjust any differences, and administer finance.

Dr. Glazebrook urged the importance of inter-school courses, and the need of greater facilities to teachers and post-graduate students for carrying out research work at their own institutions, and also at the Imperial College of Science and Technology. Principal Skinner advocated the linking up of the polytechnics to the Imperial College, but did not wish to break connection with the pure science side of the university. His polytechnic was already "thrusting itself into the Imperial College," as Sir Alfred Keogh had urged all polytechnics to do, and was doing inter-collegiate work with it. Mr. J. Wilson emphasised the difficulty of procuring under present conditions that freedom of the faculties which was so necessary. Messrs. H. Ade Clark and W. J. Lineham urged for complete separation on the grounds that sympathy towards technical work was not likely to be forthcoming from the present university. Mr. W. P. Winter urged the adoption of a wider matriculation examination, which would allow a student to qualify without having to take a foreign language. Mr. E. Bates also spoke on behalf of the building trades. Dr. Glazebrook, replying to a vote of thanks, hoped the conference would help to strengthen the evidence which the association had been asked to present to the Royal Commission.

THE DOMINION OBSERVATORY, CANADA.

THE annual reports issued by Dr. King, the chief astronomer, dealing with the work performed at, and by, the Dominion Observatory, are comprehensive volumes worthy of a place on the library shelves of every observatory for the purpose of general reference.

The organisation of a modern astronomical institution is no mean task, and to have the experiments, failures, and successes so clearly set forth as they are in these volumes, for the work is still in progress, is to be counted as one of the important achievements of the Canadian astronomers.

Perhaps the most striking feature of the organisation of astronomical labours in Canada is the manner in which collateral and interdependent researches are brought under the same direction. Dr. King's directorship includes

Observing Tower, 87 feet high, near Bowesville.

seismology, terrestrial magnetism and gravity, astrophysics, meridian work and time service, longitude and latitude observations, spectroscopy and solar physics, with all their subdivisions and ramifications. Such organisation makes for a great saving of time and correspondence; records of one branch are readily available, on the spot, for correlation with those of other branches, and auxiliary researches, such as can be more readily prosecuted in divisions other than that in which the results are actually required, can be readily ordered by the same direction. Unfortunately in this country we, at present, lack such a properly organised institution, although in other countries the opportunity and money to instal them have been found.

The report published in 1910 deals with the work done during the year ending March 31, 1908, and, in 356 pages, includes seven divisional reports, not merely of the work attempted, but the actual results in each division. A few only of the more striking features may be summarised here.

Dr. Klotz is responsible for the geophysical department, and he discusses very thoroughly the working and improvement of the seismographs, &c., and enters into a general discussion of the results. Regarding the suggestion that the boom acts as a delicate barometer, registering the tilting produced by excess or defect of atmospheric pressure, he, as yet, preserves an open mind, although the preliminary discussion of the results, given in detail in the report, indicates a connection between the presence of a "low" over the Gulf of St. Lawrence and the incidence of well-marked microseisms at Ottawa later in the same day. But there are important outstanding differences which call for further investigations.

The magnetic elements, and their variations, are also recorded in full, and the isogonic lines for 1907 are shown on an excellent large map of Canada accompanying the report.

Mr. Plaskett contributes a voluminous and important report on the astrophysical work (pp. 65–273), in which a prominent feature is the investigation of spectroscopic binaries. Those conversant with Mr. Plaskett's published papers will readily understand that a great deal of practical information concerning the apparatus and methods employed makes his report both interesting and useful for reference to those engaged in similar researches. For each star dealt with practically every possible datum is recorded, and the results are carefully summarised and discussed.

Five appendices to Mr. Plaskett's report deal with special researches coming under the head of astrophysics. Of these Mr. Harper contributes two, dealing, respectively, with the orbits of the spectroscopic binaries η Virginis and θ Aquilæ. Mr. Motherwell discusses the measurement of visually double stars, Dr. De Lury gives an account of the determination of the wave-lengths in the spark spectrum of iron-vanadium alloy between $\lambda\lambda$ 3900 and 4900, and Mr. Tobey discusses the photometric observations.

For solar work, the observatory is equipped with a 23-foot plane-grating spectroscope, used with a cœlostat and photographs of the sun, 7½ inches to the solar disc, are taken on every clear day, but during the period covered by the report the solar work was delayed by difficulties in getting the necessary buildings completed.

Mr. Stewart's report on the meridian work and time service also contains many practical hints useful to those engaged in similar work. The observatory controls a number of synchronised public clocks, and the methods of synchronisation are carefully described. Difficulties with the various piers, which cracked under the influence of frost, interfered with the meridian work to some extent, but the account of them affords instructive reading. The primary azimuth-marks are now installed underground, as at the Cape Observatory.

It is interesting to note here the great advantages secured by having a properly equipped workshop attached to the observatory, an institution without which any observatory where a number of instruments are employed in experimental researches is sadly handicapped. At Ottawa—as at Mount Wilson, Mount Hamilton, and many other important observatories—apparatus can be made, or modified, and adapted under the actual supervision of the observer who wishes to use it; and a great deal of time, trouble, and expense often required to instruct the sometimes unadaptable outside mechanician is thereby saved. While there is some satisfaction in constructing an effective piece of apparatus from odd pieces of wood and metal, with the aid of a penknife, the results attained are not, inevitably, always the most satisfactory attainable for the purpose.

The results of the latitude and longitude observations, 1907, are tabulated by Mr. Macara in Appendix 4, and the astronomical stations established up to March 31, 1908, are shown on a large-scale map of the Dominion which accompanies the report. Appendix 6 is a summary of the photographic work, and in the next section Dr. King reprints his paper, from *The Astrophysical Journal*, on the determination of the orbits of spectroscopic binaries.

The geodetic work, whilst primarily utilitarian in character, aspires to take its place among the "great" surveys—for the determination of the earth's figure—and, judging from the results given in Mr. Bigger's most interesting report, it will not be found wanting in pre-

cision. A great deal of work has been performed since its initiation in 1905, despite the fact that the atmospheric conditions in Canada were found to hamper the observations considerably. Very careful investigations of the local, actual conditions have to precede the making of the standard observations. Observing towers—modifications of that designed by Sergeant Beaton—have to be employed, and range in height from 47 to 102 feet; they consist of a tripod upon which the theodolite is mounted, and a scaffold insulating the observer's weight from the instrument. One of these structures, 87 feet high, is illustrated on p. 160, and Mr. Bigger reproduces several other photographs illustrating the method of its erection. The large amount of country already surveyed, and under survey, is shown on the third large map accompanying the report.

In conclusion, it may be stated that the report indicates that astronomy and its allied sciences are being well looked after in the Dominion with an organisation that many workers in the British Isles might well envy, and that, when completed, the Dominion Observatory will properly take its place among the observatories of the world.

W. E. ROLSTON.

A CONSPECTUS OF SCIENCE.

THE annual report of the Board of Regents of the Smithsonian Institution for the year ended June 30, 1909, has been received from Washington. The volume contains the annual report of the secretary, giving an account of the operations and condition of the institution for the year; a report of the executive committee exhibiting the financial affairs of the institution; the proceedings of the Board of Regents; and a general appendix. As in previous years, it is the appendix which gives the volume its unique value. It comprises a selection of scientific and other memoirs of wide interest relating chiefly to the year 1909. Many of these memoirs are translated into English from the languages in which they were written, and thus become much more widely available both in this country and America.

We note among such contributions to the appendix Prof. H. Poincaré's address on the future of mathematics, delivered at the International Congress of Mathematicians in Rome in 1908; Commandant Paul Renard's contribution to the *Revue des Deux Mondes* for November 1, 1909, on what constitutes superiority in an airship; M. L. Marchis' article on the production of low temperatures and refrigeration, in the *Revue générale des Sciences,* March 15, 1909; M. A. de la Baume Pluvinel's paper on solar-radiation researches by Jules César Janssen, from the *Astrophysical Journal,* September, 1908; Dr. Gaubert's essay on the formation, growth, and habit of crystals, which appeared in the *Revue scientifique* of January 15, 1909; M. Maurice Zimmermann's paper from the *Annales de Géographie,* March 15, 1909, on the Antarctic land of Victoria; M. D. Damas' paper on the oceanography of the sea of Greenland, from *La Géographie,* Paris, June 15, 1909; M. Romuald Minkiewicz's contribution to the *Revue générale des Sciences,* February 15, 1909, on the instinct of self-concealment and the choice of colours in the Crustacea; and M. G. Marotel's paper on the relation of mosquitoes, flies, ticks, fleas, and other arthropods to pathology, from the *Annales de la Société d'Agriculture, Sciences et Industrie de Lyon,* 1906.

The appendix also contains several important contributions from British men of science in the form of reprinted addresses. The numerous plates contained in the volume add greatly to its interest.

INSECT AND FUNGOID PESTS.

PROBABLY the most important advances in agricultural and horticultural practice in the present day are in the direction of controlling insect and fungoid pests. Economic considerations generally compel the grower to aim at large crops; in consequence, losses caused by disease may be very heavy. All the conditions of modern cultivation tend to favour the pests; the distribution of seeds and of nursery stock from district to district facilitates the spread of spores and ova, whilst the dense planting and the continuous cropping provide a succession of host plants. Further, the high nitrogenous manuring invariably practised as agriculture and horticulture become more developed seems to increase the susceptibility of the plant to attack. In all countries where agriculture is progressing there is growing up an enormous literature dealing with these pests. A few of the more recent publications only are referred to in this article, but the list does not profess to be complete. Two general methods are in use for combating the pests: natural enemies are encouraged, and, if necessary, introduced into the country, and poisons are applied sufficiently potent to kill the pest, but not the infested plant.

In output of literature the United States easily heads the list. Under the direction of Dr. Howard, the Bureau of Entomology of the Department of Agriculture has accomplished an enormous amount of work of both scientific and technical value. A recent bulletin by H. E. Burke deals with the flat-headed borers (Agrilus), causing damage to forest trees to the extent, it is estimated, of 100,000,000 dollars annually in the States alone. Methods of treatment are now known, and much of the damage can be prevented. The San José scale (*Aspidiotus perniciosus*) is shown by A. L. Quaintance to yield to treatment with petroleum or kerosene washes, or with lime and sulphur washes. "Brown rot" (*Sclerotinia fructigena*) and the plum curculio (*Conotrachelus nenuphar*) are described by W. M. Scott and A. L. Quaintance as causing great injury to peaches and plums respectively, but they can be kept in check by a lime-sulphur wash containing lead arsenate. V. L. Wildermuth writes on the clover-root curculio (*Sitones hispidulus*), which injures clover, although it is probably not a common pest. It is eaten by a number of birds, and, in the larval stage, is attacked by a fungus. W. M. Russell describes a cigar-case bearer (*Coleophora caryaefoliella*) attacking pecari trees; it is not yet abundant, and can probably be kept in check by lead arsenate washes. H. O. Marsh deals with the common Colorado ant (*Formica cinereorufibarbis*), which has fallen under the ban because it protects the melon aphis. It is said to be a common thing to see the ants busily engaged in killing and carrying off the syrphid larvæ which were destroying the aphides. Adults of a lady-bird, *Hippodamia convergens*, the nabid bug, *Reduviolus ferus*, and a species of Chrysopa were also carried away by the ants. The simplest method of extermination seemed to be watering the nests with a weak solution of potassium cyanide.

Not only at the Department of Agriculture, but also at the colleges, are investigations undertaken, and a large number of bulletins are issued. Many of these make no claim to originality, and are mainly of interest to us as showing how the American colleges try to educate the farmers. These bulletins are always well illustrated, pictures being given of typical infested plants and of the pest in its various stages, so that recognition shall be easy. Preventive and curative methods are described where known, and farmers are told where they may apply for further information. Admirable bulletins of this class are sent out by the agricultural experiment stations of the West Virginia University, the Purdue University, the Colorado Agricultural College, and others.

Turning to the British Dominions, good work is being done in India, and is published in the Pusa Memoirs and *The Agricultural Journal of India*. The Transvaal work appears in *The Transvaal Agricultural Journal*. In a recent issue of *The Agricultural Journal of the Cape of Good Hope*, Messrs. Laws and Manning discuss the eradication of ticks on the veld. Of the three methods in vogue, periodical dipping or spraying of the hosts, grass burning, and the enclosing of definite areas for a sufficient length of time to ensure all ticks dying off through the absence of hosts, they consider the dipping or spraying the best, but the other two are also effective. In another article the ostrich wire-worm (*Strongylus douglassii*), a worm found in the proventriculus of the ostrich, is described; the treatment commonly adopted is to give a strong dose of carbolic acid, insufficient, of course, to kill the bird. It is not considered, however, that this treatment is satisfactory, and others are discussed, but none can be depended upon as certain.

The scientific work of the entomological staff of the

West Indies appears in the West Indian Bulletin, and the more technical work in *The Agricultural News*. Mr. F. W. South deals in a recent issue of the Bulletin with the control of scale insects by means of fungoid parasites. The fungi can be introduced in two ways: material containing fructifications may be hung on the tree near to the scale-infested part, or the fructifications may be stirred up with water, which is then sprayed on to the tree. When the spores germinate, the hyphæ grow under the scales and destroy the insects. In every issue of *The Agricultural News* a section is devoted to insect and fungoid pests; the diseases of rubber trees have recently received considerable attention. Some of the islands, as Jamaica and Trinidad, issue their own bulletins, in which the staff publications appear. In the Trinidad bulletin Mr. Rorer deals with pod-rot, canker, and chupon-wilt of cacao in a well-illustrated paper; spraying is shown to be effective, but definite instructions cannot yet be given owing to the absence of local experience of the treatment.

The Circulars and Agricultural Journal of the Royal Botanic Gardens, Ceylon, contain accounts, by T. Petch, of root diseases of Hevea and of *Acacia decurrens*, which is extensively planted as a wind-break in tea plantations and also for green manuring. The brown root disease, caused by *Hymenochaete noxia*, is the commonest root disease of Hevea in Ceylon, although this fungus does less damage than *Fomes semitostus*. *Sphaerostilbe repens* is also recorded, but is as yet not common. Two diseases of Acacia are described, one caused by an agaric, *Armillaria fuscipes*, the other by *Fomes australis*. A remarkable plague of a large snail, *Achatina fulica*, is described by E. E. Green, which swarms in millions in one area of the island. On the whole, it is considered to do more good than harm, as it feeds on animal and human excrement, and does comparatively little damage to the vegetation. Besides the circulars and journal, a series of leaflets are sent out from Ceylon.

Much of the Japanese work is published in the Journal of the College of Agriculture, Tokio, a beautifully illustrated periodical brought out in English and German. Vol. ii., No. 4, contains a paper by Ichiro Miyake on the fungi attacking rice. The list is, the author believes, complete, and as full references and descriptions are given, it must prove extremely valuable to other workers. It is in the true scientific spirit that the Japanese have broken down the barrier of language and issued their scientific publications in languages that can be read in the West.

In addition to the work going on at some of the larger agricultural colleges and departments in Great Britain, the smaller colleges are also studying the pests and diseases that occur in their districts. Mr. G. T. Malthouse recently, in a bulletin issued by the Harper-Adams Agricultural College, dealt with the wart disease of potatoes (*Chrysophlyctis endobiotica*), which has been doing much damage in Shropshire and Staffordshire. Accounts of the various diseases are also circulated as leaflets by the Board of Agriculture, as well as in their Journal.

TECHNICAL INSTRUCTION AND SECONDARY SCHOOLS.[1]

TECHNICAL instruction, in particular, has too long been looked upon as having little relation to the elementary or secondary schools. The schoolmaster has perhaps been too apt to view the technical school or college as an upstart and an interloper, the title of which to the name of an educational institution rests on a very insecure foundation, and the utilitarianism of which gives a somewhat unfair advantage in the competition for students. On the other hand, those engaged in technical work have in some cases looked upon the schoolmaster as an unpractical person, from whose clutches the student should be rescued at the earliest possible moment.

We have, however, now emerged from this stage, and are ready to discuss the relationships of our various schools with a better knowledge of the necessities and limitations of each, and taking as the basis the requirements of the scholar and not the supposed benefit to the school.

[1] An address read to the Annual Congress of the Secondary Schools Association, held at Bradford on February 24, by Prof. Walter M. Gardner.

The scholar's work, from entering the elementary school to the end of his studentship, whenever that may be, should appear to him as an unbroken progress, during which he can see gradually unfolding a definite scheme leading eventually to his life's career. In so far as the various grades of education form a series of detached schemes without proper interrelationship, and to the extent to which the student's time is wasted when he passes from one grade to another by reason of this, to that degree our educational administration is defective, and we, as administrators, are lacking in skill or in our duty to the students and to the public. The solution of this problem proves to be very difficult, and even now the matter hardly receives the attention which it deserves. To provide in a sufficiently economical manner courses throughout the school suited to the different needs and capacities of various scholars is *the* educational problem. At what stage to introduce differentiation, and when to begin specialisation, and at what age a scholar should pass from one school to another—these are important but minor matters incidental to the main problem.

Keeping to the front the thought of the ultimate benefit of the student, and making this the determining factor, many details will settle themselves. Difficulties, of course, at once arise, due to the uncertainty or to differences of opinion as to whether a particular course of action is or is not for the benefit of the scholar. Here ideals will probably at once clash with practicabilities, and, as the head of a technical institution, I am perhaps predisposed to lay stress on the latter.

The problem presents itself to me in this form:—"How can we make the best use of the student's time up to the age when experience shows he will, in all probability, leave school, and what portion of this should be allocated to technical instruction?" Others may state it thus:—"In order to acquire a thoroughly trained intellect and well-stored mind, a student should pass from the elementary school at twelve or thirteen years of age to the secondary school, and should remain at the latter for at least four or five years. He cannot, therefore, enter a technical school under the age of seventeen or eighteen." How are we to reconcile these views?

Whilst it is, of course, true that all of us, men and women alike, and whatever our avocation, are of greater service, are more efficient, if we have received some training which may legitimately be termed "technical," we are not concerned with this general aspect of the subject on this occasion, but with that specialised technical instruction provided in the technical institutions. The students we wish to get in such institutions are those who will pass into the great industries of the country; and in investigating this matter we are at once confronted with the fundamental point that, of a thousand boys who pass through the elementary schools and who ultimately take positions as workmen, foremen, or managers in industrial concerns, probably not more than forty pass through a secondary school, and not more than three or four enter a day technical college. There is, therefore, a problem of enormous magnitude still requiring solution relative to the further instruction of the 950 out of every thousand boys who do not proceed beyond the elementary schools.

Before the advent of steam-driven machinery, when industrial conditions were much simpler, the personal instructions which the boys received under the apprenticeship system sufficed to produce the necessary skill and training, though in a very unequal degree. The personal association of the craftsmaster and the learner cannot, however, be relied upon under modern industrial conditions, and therefore the technical schools are called upon to provide a substitute for the apprenticeship system. Boys leaving the elementary schools are not, however, sufficiently mature to reap the full benefit of the advanced specialised instruction provided in day technical schools, and for these boys, most of whom will eventually become industrial operatives, I strongly advocate the establishment of what are known as trade preparatory schools, with a two years' course comprising, roughly, two-thirds general subjects and one-third handicraft work. The majority of the boys should then go to work and attend evening technical courses, but those who show special promise should be drafted into the day courses of the technical school by means of scholarships. A necessary and

important link is thus formed between the elementary schools and the technical institutions, which link cannot be so efficiently provided by the evening continuation schools.

Such trade preparatory schools in no way interfere with the secondary schools. They simply provide for the further education of those boys who would not, in any event, go forward to the secondary schools. It is, however, obvious that the secondary schools must constitute the main feeder of the higher day technical courses, and it is this aspect of the general question with which we are chiefly concerned this afternoon.

With regard to the relationship between the secondary and technical schools, difficult and thorny questions at once crowd into the mind. At what age should the student pass from the secondary to the technical school? Should this age be the same, whatever the student's future career is likely to be? Should the secondary-school curriculum be the same for students who are going forward to a technical school as for those who are going into commerce or into one of the professions? If not, when should differentiation begin? Should any definite technical training (using the expression in the narrow sense of special training for industrial life) be given in the secondary school?

To not one of these inquiries can a categorical reply be given.

I am not at the present moment at all concerned with Government regulations as to age or curricula, but, looking at the age question purely from the point of view of the student's benefit, one cannot lose sight of the fact that the age at which the student should finally complete his school career depends on the nature of his future occupation; and this fact, coupled with the different requirements of various groups of students, in my opinion points strongly to the desirability, wherever numbers render it practicable, of differentiation in the secondary schools.

This raises the important question as to whether different groups of subjects may be made to yield similar educational results. If this is not so, differentiation must lapse; but many will probably agree that a study of science may be made as useful in developing intellectual capacity and character as an exclusive study of the humanities, and that as liberal an education may be got from literature and science as from entire devotion to languages, living or dead.

While speaking on this matter, I should further like to urge that education and culture, in the truest sense, may be acquired during the study of the processes involved in the transformation of raw materials into useful articles, which is the special business of the technical schools. The fact that present-day factory conditions are not perhaps conducive to the development of culture does not necessarily imply that educational ideals are inherently impossible in a technical school, but, on the other hand, emphasises the necessity of their development.

I argue, therefore, that a student's education, in the strictest sense of the word, is continued during a properly organised technical course, and must entirely dissent from the view that technical instruction is purely utilitarian.

We now come to close quarters with the question of the previous training desirable for students who will enter a technical college after passing through a secondary school.

May I point out in this connection that the value of the training in many secondary schools—speaking now of the information gained rather than the intellectual training—varies greatly according to the students' future work? If a lad is going to be a clerk, it so happens that most of the ordinary school subjects are such as will eventually form his tools in his trade of clerking. Of course, for higher commercial work he requires special instruction, but up to a certain point he receives his technical training incidentally along with the ordinary school training.

In the case of students who will enter the industries this does not hold good to anything approaching the same degree, and if it is possible to place these students on an equality in this respect by modifying the secondary-school curriculum, the gain to the technical schools will be enormous.

What, then, are the possibilities in this direction? With regard to the specialised technical work, I think nothing can be done. The importance of technical instruction being given by men having an intimate knowledge of the particular branch of industry concerned cannot be overrated, and such men are not likely to be found on the staffs of secondary schools, where, in fact, they would be out of place.

Manufacturing operations, and the technical instruction dealing with them, are, however, based on scientific fact, and mainly upon physical, mechanical, and chemical science, and a knowledge of these underlying sciences should precede the technical study of materials and processes. Men highly qualified to teach these sciences are, moreover, normally found on the staffs of secondary schools, and the teaching of physics, mechanics and chemistry, and of mathematics and art, might well be carried much further than is usually the case if it is done by the right men in the right way.

This, in my opinion, is the direction for advance. What we really need in the technical colleges are students with as much sound scientific training as possible—students trained to think for themselves and with the work habit highly developed. By economising time, this would enable us to carry students further forward, to the ultimate benefit of the industries of the country.

The whole matter is one which requires sympathetic consideration from both sides, and only in this way can any real advance be made. The teachers in the secondary and technical schools should be brought closer together, should have a more intimate knowledge of each other's work, and wherever practicable, as in a large city, the curriculum of at least one of the secondary schools should be so arranged as to offer to industrial students the same advantages as are now given in such generous measure to those who are training for commercial life or for the teaching and other professions.

CRYSTALLINE STRUCTURE, MINERAL, CHEMICAL, AND LIQUID.[1]

THE importance of crystallography has been growing so rapidly during recent years that the subject is no longer to be regarded merely as a branch of geology and mineralogy, but has now become a wide and far-reaching subject on its own account, embracing its former parent mineralogy, almost the whole of solid optics, the structure and physical properties, both mechanical and thermal, of solid matter, the structure and character of metals, with most important reference to their preparation for industrial application, and the fundamental groundwork of chemistry. Such a subject can no longer with impunity be relegated to a subsidiary part of a course in geology and mineralogy, but must in future be treated, studied, and taught as a specific branch of natural science. It is of the utmost urgency that all students of chemistry, physics, mineralogy, and metallurgy should be made acquainted with the main facts of the science in order that they may understand their own subjects with clear and broad insight.

It is a remarkable fact that no definition of life has yet been given which will not include a crystal. The virility and longevity of seeds and spores are often found to be quite extraordinary; but the power of crystalline growth goes even further, for it is everlasting. An instance was taken in the first lecture from common sand grains, which, originally quartz crystals in a granitic rock, after passing through every variety of vicissitude for thousands of years, when eventually they come in contact with water containing a little of their substance, silica, in solution, begin to grow again as crystals of quartz. A slide of such sand grains was shown on the screen, having perfect little quartz prisms and pyramids growing out from them.

Some fine examples of the growth of crystals were projected on the screen in polarised and ordinary light, notably of benzoic acid crystallising from the melted condition, of white arsenic crystals growing from the vaporous state, and of potassium bichromate and ammonium chloride growing from solutions of different degrees of supersaturation. Especial emphasis was laid on the fact that slow growth from the slightly supersaturated condition, that which has been so clearly defined

[1] Summary of three lectures delivered at the Royal Institution on February 28, March 7, and March 14, by Dr. A. E. H. Tutton, F.R.S.

by Miers and Ostwald as the "metastable" condition, usually yields well-formed individual crystals suitable for study and measurement, whereas crystallisations from more strongly supersaturated solutions, those in the "labile" condition, invariably take the character of skeletal, tree-like, or acicular forms, very beautiful, but unsuitable for crystal measurement. The extraordinary fact was then referred to that germ-crystals of all common crystalline substances are constantly floating about in the air, and that by falling into metastable solutions of their own or similarly constituted (isomorphous) substances are able to set them crystallising. Indeed, metastable solutions are entirely dependent on such intrusions of germ-crystals, for labile solutions are alone capable of spontaneous crystallisation.

The great diversity of habit of the crystals of the same substance was next discussed, and a striking instance given in the three common forms of calcite, carbonate of lime, namely, the rhombs of Iceland spar, the scalenohedral (pyramidal) dog-tooth spar, and the long prismatic form of calcspar terminated by rhombohedra. Totally dissimilar specimens of all three were exhibited, and others still more remarkable, from the same mine, were projected on the screen, so unlike as to be apparently the crystals of quite different substances. Yet the faces present were geometrically the same, but developed to different extents, in all three, and inclined at angles of precisely the same value. It was shown how this diversity of habit had delayed the discovery of the laws of crystallography, and the historic sequence of events, from the seventeenth century onwards, was briefly outlined, until in 1784 the main laws were enunciated by the Abbe Haüy, especially the great law of the constancy of the angles of the crystals of the same substance.

The natural classification of crystals into seven styles of architecture or crystal systems, according to the geometrical disposition of their faces, was then discussed, and shown to depend on the presence of a greater or less number of planes and axes of symmetry, this external configuration being due to the regular homogeneous character of the internal structure. It was shown that this latter is of the nature of a space-lattice, each unit cell of which is occupied by a chemical molecule. The chemical molecules are thus the regularly arranged bricks of the crystal edifice. Some remarkable examples of crystals of the various seven systems were exhibited, both in the form of natural mineral crystals of large size, and of artificial crystals, some of considerable size and others grown under the microscope, photographs of many such crystals taken in the act of growth being exhibited on the screen.

The grouping of crystal faces in "forms" or sets having an equal value with respect to the symmetry, and the mode of distinguishing the faces by their "indices," symbols of three or four figures (inversely proportional to the lengths of the axes cut off by the face) enclosed within brackets, was explained. The simple or "rational" nature of these indices, the low numbers, 1, 2, 3, and 4 vastly predominating, and being often the only numbers involved, was emphasised, thus demonstrating the important law of rational indices.

It was shown in the second lecture that these external regularities are entirely the consequence of the internal homogeneity and structural symmetry of the molecular arrangement in one or other of the fourteen space-lattices referred to in the first lecture. The remarkable work of Sohncke, Schönflies, von Fedorow, and Barlow was then discussed, whose joint labours had indicated 230 types of homogeneous structure, represented by point-systems, and which include 165 involving the property of mirror-image symmetry and 65 Sohnckian assemblages of points which do not, but clusters of which latter, if each cluster be represented by a single point, give us the 14 space-lattices. The interesting fact was brought out that the space-lattice represents, in all the simpler cases, the arrangement of the molecules, while the detailed point-system represents the plan of distribution of the atoms.

It was also shown how recent work had confirmed the law of Haüy as to the constancy and specific nature of the crystal angles of any one substance, and that in the cases of the isomorphous series of Mitscherlich, composed of analogously constituted compounds, which were at first supposed to be identical in their crystal morphology, the crystals of the different members of the series show small but real differences in their angles, and even greater differences in their other properties. Moreover, the differences conform to a definite law, for they follow the order of progression of the atomic weights of the interchangeable chemical elements which give rise to the series. The dimensions of the structural-unit molecular cells of the space-lattice also conform to this law.

The optical properties of crystals may, in general, be represented by an ellipsoid, the three rectangular axes of which are proportional to the three different refractive indices afforded along those directions, and the position of which varies with the symmetry. Crystals of the rhombic, monoclinic, and triclinic systems have such a triaxial ellipsoid, but it becomes an ellipsoid of revolution for crystals of the tetragonal, hexagonal, and trigonal systems, and a sphere for a cubic crystal. This property thus at once enables us to discriminate between these three groups of crystal systems, which are characterised, respectively, by three indices, two indices, and one index of refraction. The directions of the three axes of the ellipsoid are identical with the crystallographic ones in a rhombic crystal, but only one axis is coincident with a crystal-axis in a monoclinic crystal, and no axes are coincident in a triclinic crystal.

Such an ellipsoid with three unequal rectangular axes must possess two circular sections symmetrically situated, and directions perpendicular to these sections are the well-known optic axes of "biaxial" crystals, more or less comparable to the single axis of no double refraction of "uniaxial" crystals, which are characterised by an ellipsoid of revolution. It is round these two optic axial directions that the well-known spectrum-coloured rings and dark hyperbolic "brushes" are visible in convergent polarised light, thus forming the biaxial analogue of the circular spectrum-rings and black rectangular cross of a uniaxial crystal such as calcite. Many of these phenomena were projected on the screen with the projection polariscope, including the Mitscherlich experiment showing the crossing of the optic axial plane of gypsum as the crystal becomes warmed by the heat rays accompanying the beam of convergent light.

The concluding lecture opened with a description of the remarkable "liquid crystals" discovered by Lehmann, substances of complicated and elongated chain-like chemical constitution, the molecules of which set themselves, by virtue of their inherent directive force, in shapes resembling crystals, which display double refraction and rotate the plane of polarisation. Mobile crystals of para-azoxyanisol in the form of rotating drops, of the ethyl ester of para-azoxy-benzoic acid, and of para-azoxy-phenetol in the shape of rounded crystals showing interference bands, were exhibited on the screen with the Zeiss projection microscope, and also spherulites of cholesteryl acetate, beautiful star-like apparitions breaking out all over the field, exhibiting colours and a dark cross in polarised light. The mobile crystals were instantly deformed on touching the cover-glass, but as instantly recovered their shape on removing the pressure.

The conclusion arrived at from experiments of this nature was that the molecular directive force of crystallisation, temporarily discarded as unnecessary by the geometricians for the building up of homogeneous structures, is reinstated as a fact which cannot be ignored. There can be no doubt that in these mobile crystals the chemical molecules are constantly arranging themselves in space-lattices, although the substance may be as mobile as water. The fundamental importance of the space-lattice, its formation by the chemical molecules as its structural units, and its influence in determining the crystal system, are thus again strongly emphasised.

It was proved by various optical devices that crystals of quartz exhibiting characteristic little facets on certain right-hand solid angles invariably rotate the plane of polarisation to the right, while other crystals on which these faces are only developed on the left-hand solid angles rotate the polarised rays to the left. It was further proved that this was due to an oppositely right-handed and left-handed helical arrangement of the atoms composing the molecules in the two cases, and that there are equal chances in nature for the formation of either. The re-

markable optical effects of the twinning of right- and left-handed quartz were also demonstrated, culminating in the interesting case of lamination twinning of amethyst; and interesting conclusions were drawn as to the chemical nature of the racemic, pseudo-racemic, and truly inactive varieties of substances showing the optically active forms.

It was made clear during these lectures how important crystallography is to chemistry. This importance has, however, been yet further enhanced by the recent work of Pope and Barlow, who have shown that the fundamental chemical property of valency is intimately connected with crystalline structure; for if we assume, as there is ground for doing, that the atoms present in a crystal may be represented by their spheres of influence arranged in contact, according to the particular type of homogeneous structure displayed, then the volumes of these spheres of influence are proportional in any one compound to the fundamental chemical valency of the atoms. This theory, when taken in conjunction with the lecturer's work on isomorphous series, in which the progression of the crystal properties was shown to follow that of the atomic weights of the interchangeable elements of the same family group forming the series, embraces the whole field of chemistry, the theory of Pope and Barlow relating to the horizontal progression and the generalisation concerning isomorphous series corresponding to the vertical progression of the periodic law of Mendeléeff. The importance of crystallography to chemistry is thus not only paramount, but fundamental.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

IT is announced that Miss Mary Anne Ewart, who died on February 19, left 20,000*l.* to Newnham College, Cambridge, for scholarships for the benefit of women students studying there, and 10,000*l.* to Somerville College, Oxford, for like purposes.

A SHORT time ago announcement was made that the late M. A. Loutreuil had left the sum of 284,000*l.* for the promotion of science in France. Of this amount, 100,000*l.* was bequeathed to the University of Paris upon condition that the provincial universities also should benefit by the annual revenue derived from this sum. A message from Paris, published in *The Times* of March 29, states that a committee consisting of the Vice-Rector of the Sorbonne and a representative of the faculty of science of each of the provincial universities will decide the distribution of the revenue from the legacy, and will communicate its decisions to the council of the University of Paris. According to the terms of the will, the revenue of the gift is to be devoted to the encouragement of scientific studies, the equipment of laboratories, the formation of a library, and the foundation of additional lectureships on scientific subjects.

THE president's address to the members of the Institution of Mechanical Engineers was delivered on March 16. Mr. Ellington considered questions relating to the qualifications for membership; the Institution of Civil Engineers has already attained to a position such that it is difficult for civil engineers who are outside that body to obtain positions of responsibility. That the Institution of Mechanical Engineers is the proper body to secure the same standing for mechanical engineers is undoubted. Mr. Ellington insists on knowledge and experience in both theory and practice of mechanical engineering as essentials for admission, and would favour examinations for entrance to the grade of associate member. The council of the institution has always closely scrutinised the educational training and practical experience of candidates for membership, and properly conducted examinations would provide a desirable standard of entrance into the profession.

THE sum of 1400*l.*, says *Science*, has been received by the University of Michigan from the estate of Emma J. Cole, of Grand Rapids, Michigan, to constitute a scholarship fund for graduate students in botany. From the same source we learn that the regents of the University of Wisconsin have accepted as a trust the sum of 6060*l.* for the establishment and maintenance of a chair to be known as the Carl Schurz memorial professorship. The chair is to be filled by professors from the universities of Germany. The present fund will make it possible to secure a German professor for one semester every second year. President Van Hise has been authorised to open negotiations with German authorities with the view of establishing a system of exchange professors between German universities and the University of Wisconsin. The establishment of the Carl Schurz professorship will be celebrated on March 31. The speakers on that occasion will include the two German exchange professors now in the States, Dr. Max Friedlaender, of the University of Berlin, now at Harvard, and Prof. Ernst Daenell, of the University of Kiel, Kaiser Wilhelm professor at Columbia.

THE trustees of the A.K. Travelling Fellowships will shortly elect two fellows. These fellowships, for which both men and women are eligible, are each of the value of 660*l.*, are awarded annually, and, as has been explained in these columns, were established for the purpose of enabling the fellows to travel round the world. The trust is administered at the University of London. The appointments are made by a board of trustees, and candidates are nominated by the Vice-Chancellors of each of the universities of the United Kingdom, the president of the Royal Society, and the president of the British Academy, but the trustees are not required to confine their election to these nominees. The only conditions for candidature are that candidates shall be British subjects and graduates of, or persons who have passed all the examinations required for a degree in, some university of the United Kingdom. An incorrect impression exists that persons to be nominated as candidates must be members of the teaching profession in one of its grades. The founder's object in establishing the fellowships is in no sense to further any special line of research, but to enable intellectual men to enter into personal contact with men and countries they might never have known. The English fellowships are part of a general scheme for the establishment of similar foundations in various countries, and endowments have been made already for this purpose in France, Germany, Japan, and the United States.

THE third annual report of the governing body of the Imperial College of Science and Technology deals with the work for the year ending July 31, 1910, and shows that the activities of the college were much extended during that period. The building extensions were pushed forward, and some are now nearly complete. The workshops of the City and Guilds College have been extended, at a cost of 8000*l.* to the City Guilds Institute, to provide for the development of the course of instruction in railway engineering commenced two years ago. We notice that the Bessemer memorial committee has decided to provide 10,000*l.* to assist in equipping the mining and metallurgical laboratories, and the laboratory so furnished will be called the Bessemer Laboratory, and in it a statue of the late Sir Henry Bessemer will be erected. The governing body has secured the services of leading men of large experience in connection with great industrial concerns of the country, or of men with special knowledge, for the purpose of giving short courses of advanced lectures on such branches of science as press for immediate study. Financial considerations prevented the full and immediate realisation of the department of chemical technology recommended by the Advisory Board concerned with this subject, but a beginning has been made, so far as is practicable, in the existing buildings. Great attention has been given by the governing body to the provision of facilities for the study of the relation of the biological sciences to the industries, and funds have been set aside for the foundation of a chair of plant physiology and pathology, and it is hoped that resources will be forthcoming for its permanent endowment. A complete scheme of scientific instruction and research in aëronautics has been drawn up, and much work has been done in providing facilities for such study. The approved budget for 1910–11 for the Imperial College as a whole estimates a revenue of 59,006*l.*, and an expenditure of 67,374*l.*—a deficit of 8368*l.*, while the estimated effect of capital commitments (buildings, &c.) will be to reduce the unappropriated capital to 100,935*l.*

IN the issue of *Science* for March 10, Prof. Rudolf Tombo, jun., deals with the statistics of students at

German universities. His article on the registration statistics of American universities, to which reference was made in these columns on March 23 (vol. lxxxvi., p. 133), leads to certain interesting comparisons. The twenty-one German universities show an enrolment for the winter semester of 1910–11 of 54,822 students, as against 52,407 students the winter before. During the past five years there has been an increase in registration of no fewer than 12,432 students. The number of women students has grown from 211 five years ago to 2418 in the present session. The number of students studying pure science is 7914 as compared with 7349 in the previous session, in agriculture 2546 as compared with 2085, and forestry 171 as compared with 129. The three largest universities —Berlin, München, and Leipzig—alone enrolled no fewer than 39 per cent. of the total German student body. Berlin remains at the top with an enrolment of 9686 students, as against 9242 last winter. This is followed by the University of München with 6905 students (6537 last year). It will be remembered that for the first time in the history of American universities the 7000 mark was passed in the last winter session, Columbia having a grand total of 7411 students. Six American universities have now more than 5000 students. In Germany, Leipzig is the third most numerously attended university, and has 4900 students. Bonn follows with 3846. Seven others have fewer than 3000 and more than 2000 students, and all but two—Greifswald and Rostock—have more than 1000 students. The figures show that all the universities, with the exception of Erlangen, Würzburg, and Giessen, have increased their attendance, the largest gains having been made by Halle, Kiel, Jena, Tübingen, and Rostock. Since 1909–10 Breslau has been passed by Halle, Göttingen by Freiburg, Heidelberg by Münster, Würzburg and Königsberg by Kiel. In addition to the 54,822 matriculated students, 3528 men and 1772 women are enrolled as auditors, giving a total of 60,122 individuals receiving instruction at the German universities, the largest number in the history of German higher education.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, March 23.—Sir Archibald Geikie, K.C.B., president, in the chair.—G. N. **Watson**: A theory of asymptotic series.—R. T. **Beatty**: The ionisation of heavy gases by X-rays.—W. **Wilson**: The variation of the ionisation with velocity for the β particles. Rays of different speeds were separated, by means of a magnetic field, from the heterogeneous beam given out by the active deposit from radium. The relative numbers of particles corresponding to the different speeds were determined by measuring the charges gained per second by an insulated copper vessel which was placed in the path of the rays, and was thick enough to absorb them completely. The corresponding ionisations were determined by a separate experiment, and were corrected for scattering of the rays by the walls of the ionisation vessel. The results obtained are as follows:—(1) The ionisation produced per cm. by β particles in free air varies inversely as the square of the velocity, between the limits examined. (2) The ionisation in a thick copper vessel is not connected with the velocity by any simple law, but can be approximately represented by $I=k(c-v)$, where I is the ionisation, v the velocity of the particles, and k and c constants.—C. G. **Douglas** and Dr. J. S. **Haldane**: The causes of absorption of oxygen by the lungs in man.—Prof. Arthur **Schuster**: The influence of planets on the formation of sun-spots. In this investigation the relative position in heliocentric longitude of a planet, and that point of the sun's disc where a spot is first observed, is taken as starting point. Spots first noticed within 60° of the eastern limb were excluded on account of the possibility or probability that these spots were formed in the invisible hemisphere, and only brought into view by the rotation. The total number of spots taken into account was about 4250. Imagine an observer placed on the sun. He might observe within each solar rotation, imagined to be divided into twenty-four hours, a planet rising, reaching a maximum altitude, called "planetary noon," descending and setting. The chief results of the investigation, dealing with the planets Mercury, Venus, and Jupiter, are as follows:—(1) More spots are formed when the planet is above the horizon than during the planetary night. The excess amounts to 4·5 per cent. in the case of Mercury, 6·4 per cent. in the case of Venus, and 1·5 per cent. in the case of Jupiter. The probability that this excess is accidental in the case of Mercury and Venus is about 1 in 7 and 1 in 17 respectively. In the case of Jupiter, the difference is no more than might be expected by the theory of chance. Not much importance is attached to each of these results taken separately, but if the theory of probability be applied to the combined results, an accidental coincidence of the excesses of one hemisphere over the other to the amounts indicated will not happen more than once in 1150 cases. (2) More decided results are obtained if the formation of spots during different parts of the planetary day are investigated. If the distribution were purely accidental, twice as many spots should form during the eight hours after the planet has risen as in the four hours before it sets. It is found, on the contrary, that during the latter interval the number of spots bears a proportion of 0·344, 0·349, and 0·347 respectively to the whole instead of 0·333, the planets always being taken in order of distance from the sun. The average excess here amounts to about 5 per cent. (3) The effect of the planets when compared in detail exhibits remarkable similarities. At an observing station on the sun, a strong minimum of spot formation is found to exist shortly before the planet rises; this is followed by a decided maximum in all three cases one hour after the rise. This is succeeded by a drop in activity, leading to a minimum, which occurs sooner with Mercury and Venus than with Jupiter, but this distinction may be accidental. The most remarkable feature in all three cases is the rapid rise from a secondary minimum, one hour after the planetary noon, to a pronounced maximum two hours later. This is followed by a drop lasting until the hour before the planet sets. The action after that and during the greater part of the planetary night is irregular, and might disappear if a larger quantity of material were available. The probability that all three planets should show their greatest activity at the same hour to the extent shown by the figures is 1 part in 130 million. The probability of the corresponding minimum in the planetary morning is not much less, so that taking the coincidence of both these factors into account, we may exclude the possibility of an accidental coincidence.

Royal Astronomical Society, March 10.—Mr. F. W. Dyson, F.R.S., president, in the chair.—Mr. Stratton gave an account of a paper by the late Mr. Bryan **Cookson**, a research on the aberration constant and the variation of latitude by means of the floating zenith telescope. The paper was left unfinished owing to the illness and death of the author, and had been completed and prepared for publication by Messrs. Hinks and Stratton. Their principal work had been to renew the search for systematic errors, and to prepare for press an account of the investigation. Sir David Gill spoke of the value of the constant of aberration obtained by Mr. Cookson. In reference to unexplained discordances, he suggested the possibility of a displacement of the zenith from meteorological causes.—Mr. Eddington gave a short account of a paper by Dr. W. **de Sitter** on the bearing of the principle of relativity in gravitational astronomy. It was assumed that mass or inertia had an electrical origin, and it had been shown that the motion of matter relatively to the æther is impossible, the author being of opinion that the æther hypothesis might be abandoned.—Mr. **Davidson** showed photographs of Jupiter's satellite VIII., taken at the Helwân Observatory, Egypt, when the planet was too far south for observation at Greenwich. There was a certain residual when compared with theory which might disappear if we assumed a small error in the tabular orbit. —Prof. **Turner** read a paper on the determination of the positions of reference stars and fundamental stars by photographic processes. He compared the superseding of visual by photographic observations to the substitution of the telescope for the old "sight" instruments, which Hevelius and Halley considered the most accurate. Sir David Gill pointed out difficulties and recommended caution, and the Astronomer Royal considered that photography could not render observations with the transit instrument unnecessary, though moving wires might be

superseded by photographic methods.—Mr. Reynolds showed photographs of Halley's comet taken by Mr. **Knox Shaw** at the Helwân Observatory, and pointed out that when the comet was near the sun the tail seemed formed from the envelopes round the nucleus, leaving a dark streak in the centre. When farther from the sun the dark streak was replaced by a bright one, the tail appearing to spring from the nucleus itself.

Linnean Society, March 16.—Dr. D. H. Scott, F.R.S., president, in the chair.—Mrs. D. H. **Scott**: New species of the fossil genus Traquairia.—R. S. **Adamson**: An ecological study of a Cambridgeshire woodland.

CAMBRIDGE.

Philosophical Society, March 13.—Sir George Darwin, K.C.B., F.R.S., president, in the chair.—Sir J. J. **Thomson**: Exhibition of photographs of Kanal Strahlen.—F. E. E. **Lamplough**: (1) Freezing point and depression of freezing point of sodium chloride. The depressions of freezing points of certain fused salts were measured by the platinum resistance thermometer. In the case of sodium chloride, the molecular depressions of the freezing point for most salts examined were nearly the same; that of sodium bromide, however, was half as great as the depression generally expected. In the case of calcium chloride as solvent, no regular results were obtained. Some unsuccessful attempts to measure directly the rate of migration of a coloured ion in fused silver nitrate, which led to the above research, were described. (2) A simple form of electric resistance furnace. A resistance furnace which may be easily set up, and is useful for many operations, such as the determination of freezing points, points of recalescence, and for slow cooling, annealing, &c., was described.—J. A. **Crowther**: Some experiments on scattered Röntgen radiation. Experiments have been made to investigate further the unsymmetrical distribution of scattered radiation already described by the author. The distribution has been shown to be unaffected by strong electric and magnetic fields. Experiments made near the primary beam have failed to detect any direct diffusion or irregular refraction of the primary beam itself.—H. E. **Watson**: Regularities in the spectrum of neon. The spectrum of neon, as previously measured by the author, has been examined with the view of finding some connection between the wave-lengths of the lines composing it. The existence of a number of triplets and quadruplets with constant oscillation frequency differences has been discovered, these being such that if A is the oscillation frequency of the first line, those of the other members are approximately $A+1070$, $A+1429$, and $A+1847$. In the case of the triplets, the second line is absent. These regularities apply only to the brightest lines of the spectrum, which fall naturally into three groups of diminishing intensity. The first group contains two very bright lines, three quadruplets, and three triplets; the second, two very bright lines, three quadruplets, and four triplets; and the third, two bright lines, three quadruplets, and five or six triplets. This type of regularity is not like that of helium, but is very similar to that part of the argon spectrum investigated by Rydberg. The investigation of the other lines is being continued.—J. C. **Chapman**: Fatigue and persistence effects in the production of secondary Röntgen rays. In these experiments a radiator was fully excited by X-rays, and its power of emitting secondary radiation was compared by a method only allowing 1/600th second for recovery from any fatigue which might exist, with that of a radiator of the same material not previously excited. The results with zinc, copper, and aluminium fail to show that any such fatigue is present. In addition, there is no measurable persistence in the production of secondary radiation from aluminium 1/8500th second after the removal of the exciting beam.—J. E. **Purvis**: The absorption spectra of the vapours of some sulphur compounds. The substances examined were diethyl trithiocarbonate, diethyl thionthiocarbonate, diethyl monothio-oxalate and dipropyl dithio-oxalate. It was found that (1) each of the vapours exhibited a large absorption band in the ultra-violet regions of the spectrum; (2) each band was comparable with the band found in the alcoholic solutions, except as regards position; (3) there was no series of narrow bands produced as a result of the freer vibrations; and (4) the general absorption was shifted towards the less refrangible regions as the temperature and pressure were increased. A discussion of these results from a consideration of the orientation of the atoms as a closed ring.—J. C. **Chapman** and E. D. **Guest**: The intensity of secondary homogeneous Röntgen radiation from compounds. The results of these experiments indicate that the same intensity of secondary homogeneous radiation is produced whether the metal which gives rise to it is combined or not, or whatever its compound.

PARIS.

Academy of Sciences, March 20.—M. Armand Gautier in the chair.—M. **Schloesing**, sen.: The mother liquors from the salt marshes. A study of the mother liquors in the salt works of Goulette, in Tunis.—E. L. **Bouvier**: The decapod Crustacea collected by the *Princesse Alice* during the voyage of 1910. For the bathypelagic fauna described, the modification of the Richard wire, due to M. Bourée, has been found to be of great service.—M. Hilbert was elected a correspondant for the section of geometry in the place of M. Dedekind, elected foreign associate.—Sigismond **Janiszewski**: Continuities irreducible between two points.—René **Garnier**: Differential equations with fixed critical points and hypergeometric functions of higher order.—G. **Reboul** and E. Grégoire **de Bollemont**: The transport of particles of certain metals under the action of heat. If a sheet of platinum is placed at a short distance from a sheet of copper, and both heated to about 800° C., a black deposit is seen to be formed on the platinum. This was proved to consist for the most part of copper oxide. The magnitude of the deposit under varying conditions has been studied.—Samuel **Lifchitz**: Displacement of particles in the Brownian movement with the aid of very rapid sound vibrations.—E. **Caudrelier**: Researches on the constitution of the electric spark. The initial state of ionisation of the gap in certain cases has an influence on the discharge of transformers, but the action is very complex. M. **Guilleminot**: The yield in secondary rays of X-rays of different quality.—A. and L. **Lumière** and A. **Seyewetz**: Differentiation by means of chemical development of the latent images obtained with emulsions of silver chloride and bromide. The special developer used contained sodium quinone-sulphonate and sodium sulphite in water. With this solution a latent image obtained in a gelatinochloride emulsion could be developed in some minutes, whilst no trace appeared in a gelatinobromide emulsion, even strongly over-exposed.—G. **Urbain** and C. **Scal**: Monovariant systems which admit of a gaseous phase.—Marcel **Dubard**: The genus Planchonella, its affinities and geographical distribution.—L. **Lindet**: The elective power of plant cells towards dextrose and levulose. Experiments on the behaviour of fungi towards dextrose and levulose confirm the results previously obtained with beetroot. Levulose is specially concerned with tissue formation, whilst dextrose is more decomposable and more easily split up by fermentation or burnt by respiration.—G. **André**: The conservation of saline materials in an annual plant; the distribution of the dry substance, total ash, and nitrogen.—M. **Marcille**: The mode of action of sulphur utilised for destroying oïdium. The author's experiments show that neither the volatilisation of sulphur nor its oxidation can be regarded as having any appreciable effect on the fungus. Sulphur appears to act upon oïdium solely by reason of the sulphuric acid which it contains ready formed.—M. **Mazé**: The influence of mineral substances which accumulate in the organs as assimilation residues upon the development of the plant. The absorption of colloidal organic materials by the roots.—Mme. Z. **Gruzewska**: Some characteristic properties of amylase and amylopectine.—M. **Tsvett**: A new plant colouring matter, thuyorhodine. The analysis of the winter pigment of Thuya has shown that there is no modification of the α and β chlorophyllines, but that there is a new red colouring matter formed, for which the name thuyorhodine is proposed. The method of extraction and properties of this substance are given in detail.—C. **Delezenne** and Mlle. S. **Ledert**: The action of cobra venom upon the serum of the horse. Its relations with hæmolysis. The experiments described lead to the conclusion that snake venom acts as a catalytic agent or a species of diastase capable of liberating at the expense of certain materials in the blood serum a substance endowed with true hæmolytic properties; this catalytic action is considerably limited

by the presence of blood corpuscles.—MM. **Doyon**, A. **Morel**, and A. **Policard**: Passage of the anti-coagulating nucleo-proteid of the liver into the blood. Comparative action of atropine according to the mode of penetration.—J. **Le Goff**: The mortality through diabetes in Paris and in the department of the Seine. In thirty years the number of deaths caused by diabetes has quadrupled. This may be due to a relative increase in the number of cases or to a higher rate of mortality per 1000 cases. The possible causes of this increase are discussed.—Jules **Courmont** and A. **Rochaix**: Immunisation through the intestine. Antityphoid vaccination. These researches were carried out on the goat, guinea-pig, rabbit, and on man. No inconvenience results to the human subject by the use of this method.—Mme. **Fabre** and A. **Zimmern** and G. **Fabre**: The action of a continuous current on the diadermic penetration of radio-active substances.—MM. **Haret, Danne,** and **Jaboin**: A new method for the introduction of radium into the tissues. The radium ions are introduced into the organism by the electrolysis of a solution of a pure radium salt.—L. **Bruntz** and L. **Spillmann**: The origin of cancers of the skin.—G. **Guilbert**: The storm of March 13, 1911.—A. **Baldit**: Observations on the electric charges of the rain in 1910 at Puy-en-Velay.

DIARY OF SOCIETIES.

THURSDAY, MARCH 30.

ROYAL SOCIETY, at 4.30.—The Chemical Dynamics of Serum Reactions: Captain A. G. McKendrick.—Preliminary Note on a Method of Measuring Colour Sensations by Intermittent Light, with Description of an Unfinished Apparatus for the Purpose: Dr. G. J. Burch, F.R.S.—On Variation and Adaptation in Bacteria, illustrated by Observations upon Streptococci; with special reference to the Value of Fermentation Tests as applied to these Organisms: E. W. A. ARTS AND INDUSTRIES IN THE ENCYCLOPAEDIA BRITANNICA.

Collection of Articles on Industries and Manufactures (loose sheets) from the New (Eleventh) Edition of the "Encyclopaedia Britannica." (Cambridge: University Press, n.d.)

THIS collection of technical articles from the *Encyclopaedia Britannica* must be taken as consisting of samples only, since it does not go beyond the first half of the alphabet—"Alkali Manufacture" to "Iron and Steel"—and even for that half it is certainly incomplete. There must be more than as many more articles which in any reasonable classification would be included in the category of technical. Hence even if the reviewer were endowed with a mind encyclopædic enough for the task, it would not be possible from the examples to criticise the work as a whole, to test it as it should be tested, by hunting up subjects with which the critic is familiar, and seeing how the work comes out of the trial. All that can be done is to take the specimens, and to form such opinion upon them as we may, minimising any deficiency in omniscience by the simple (and usual) expedient of dwelling on the familiar and ignoring the unknown. But, after all, the material is ample enough even if it be but a tenth of the whole—πλέον ἥμισυ πάντος—we really have got more than we want.

It would be too much to say that there is real uniformity in the method of treatment. Humanly that were impossible. But there is a much nearer approach to uniformity than in the older editions, so far as can be judged from the selected articles. Perhaps it would be more evident in other than the technical sections. In these there seems to have been a good deal of compression. On the whole, the articles, especially the longer articles, seem to be shorter than those in the ninth edition. Perhaps in some cases the material has been transferred to other headings. Often the historical part has disappeared, or been abbreviated. The modern articles seem more sternly practical than their predecessors. Sometimes this is a pity, and it makes one hope that not all the old series will be exchanged for the new version, and sent to be pulped. Perhaps now that we are all utilising the completed applications of science, it does not much matter how they have been developed, but to some misguided folk the history of invention is not the least interesting of the various branches of human history.

It is, of course, in the method of treatment that the various articles show a certain lack of uniformity. Some are too technical. The first on our list, "Alkali Manufacture," which seems quite new, though perhaps part of the information in it may have appeared under some other heading in the ninth edition, errs, to our mind, in this respect. It is an excellent and clearly written account of the manufacture in its modern forms, but it would be hardly intelligible to anybody who had no knowledge of chemistry. The allied articles "Bleaching" and "Dyeing," are quite different in character, and are better adapted for their immediate purpose. The expert does not need to apply for information about his own subject to an encyclopædia, and the writer of an article for an encyclopædia has no right to assume that his reader has even the small amount of technical knowledge required to make him understand the sort of article which to the expert might seem commonplace.

The article on "Electricity Supply" seems an admirable model for any writer to follow. It contains just the information which would be needed, say, for the owner of a country-house, who is thinking of installing the electric light, while it is also an admirably condensed and clear account of the latest development of the subject. "Electro-metallurgy" is good, but incomplete, no doubt because certain parts of the subjects are dealt with in articles such as "Electrochemistry," not included in our bundle.

Some of the articles are very interesting, because when compared with the corresponding articles in previous editions they show very clearly the progress of invention. Notable in this way, for instance, is "Bicycle." In 1875 the latest novelty was the old "Ordinary," really an extremely dangerous machine. The supplement had "cycling," but not "bicycle" (encyclopædia articles are wont to find themselves under the latest convenient letter of the alphabet), and now we have a very full and excellent account of the modern machine.

Other articles indicate that certain industries have changed but little in the past two and twenty years. Take "Clocks," for instance. The long and admirable treatise contributed by the late Lord Grimthorpe to the older edition has been rewritten and shortened by some three pages. If we omit the account of electrical clocks, there does not seem very much new matter in it, but a good deal appears to have been judiciously left out.

Perhaps the most important, as it is the longest, of our batch is the article on "Iron and Steel." It is much less than half the length of the corresponding article in the previous edition (some thirty-four pages as compared with eighty-four), by the late Dr. Alder Wright. The opinion may be expressed, though with considerable hesitation, since it could only be justified by a minute and careful comparison of the two articles, that on the whole the longer article of the ninth edition gave a better account of the state of the manufacture in 1881, the year of its publication, than the present one does of its condition in 1911. At the same time, it does give a full, and no doubt accurate account of recent advances, and perhaps most of what is omitted has become of little more than historical interest. As time goes on Bessemer and Mushet and Siemens must take their place with Cort and Darby and Dud Dudley, but it is early days yet for that. We should have thought that some account might have been given of the

application of the microscope to the study of metals, which, extensively applied by Roberts-Austen to the examination of alloys, has, in the hands of Rosenhain and others, so much increased our knowledge of the nature and structure of iron. Its results are fully utilised, and there are a couple of photomicrographs of iron, but the process is not described. If space were wanted, we might have spared the remarks on the evidence of design afforded by the abundance of iron, and the somewhat vague speculations as to how primitive man was led to the reduction and utilisation of the metal.

Of the three great divisions of the textile industries, only one is included in our purview. The linen and woollen trades must of necessity come later in their proper alphabetical place. Even hemp and jute belong to the second half of the list. Cotton alone comes into an early volume. It is the subject of three long and important articles, one dealing with the supply of the raw material and the trade, the second with the manufacture generally, and the third with cotton-spinning. The first of these seems very complete, and the information is brought well up to date, but the technology of the subject proper is dealt with only in the other two. The remark was made above that the history of trade and invention came in for less than its fair share of notice. This criticism certainly does not apply to the article on "Cotton Manufacture." No better summary of the history of this great industry need be desired. Doubtless it might be amplified, but that would carry it beyond reasonable limits. The author has availed himself of all the usual sources of information, and has also discovered others which are certainly not familiar to all students of the subject. It is indeed an admirable essay. The article on "Cotton-spinning Machinery" is good, but will have to be studied in connection with other articles—"Carding," "Spinning," "Weaving," &c., not included with those before us.

Another article dealing with a department of the textile industry is the one on "Carpet." This has been rewritten, and some inaccuracies in the previous edition have been set right. Alike from the historical and from the artistic point of view this is an excellent paper. As regards purely technical information it is deficient. The appended bibliography is very complete. If "Carpet" is not quite technical enough, "Damask" is nothing else, and is scarcely intelligible to a reader ignorant of weaving terms.

"Bookbinding" is a subject of such general interest that the editor might well have allotted more than five pages to it, or might have allowed his contributor the space now devoted to four large but quite unnecessary pictures of machinery. Within the narrow limits, the account of artistic binding is sufficient, but the description of machine binding is quite inadequate.

Turning now to the shorter articles, we find many which are models of what such work should be, crammed with information condensed into the smallest possible space. Potted knowledge, in fact, such as we may properly expect in an encyclopædia. Perhaps the editor found his minor contributors more amenable to his Procrustean rule than the self-willed experts upon whom he had to rely for special knowledge. Among such articles may be noted "Basket," "Fireworks," "Flax," and "Goldbeating," though many others might be mentioned.

A word of protest may be permitted about some of the illustrations. Where space is so valuable why devote whole pages to photographs of machines and factory rooms, which convey no valuable information whatever? For instance, there are four half-tone blocks, occupying two pages, which illustrate "Cotton-spinning" machinery by views of carding engines and spinning-rooms. As pictures they are ugly; as photographs they are indifferent; as conveying information they are worthless. All description of machinery and mechanism requires diagrammatic illustration, but it should be diagrammatic, not pictorial. Such illustration is abundantly provided in articles like "Clocks," "Forging," "Founding," &c., and in many cases such simple sketches might wisely have been substituted for more elaborate views of machines and apparatus, the action of which it is quite impossible to follow from a mere external picture. The phototype illustrations of carpets and of bookbindings are inoffensive and excusable, but they convey so poor an idea of the rich beauty of the coloured originals that we could do better without them.

Photographic reproductions, properly applied, are, of course, invaluable. The photomicrographs of fibres in the article on that subject show structure in a way that no other pictorial device could show it, and the same remark applies to the magnified views of sections of iron given in the article on "Iron and Steel."

ORGANIC CHEMISTRY OF NITROGEN.

The Organic Chemistry of Nitrogen. By Dr. Nevil Vincent Sidgwick. Pp. xii+415. (Oxford: Clarendon Press, 1910.) Price 14*s.* net.

THIS book will be welcomed by students of organic chemistry as one of the highly desirable monographs which, unfortunately, have been so rarely produced in this country.

In the preface the author informs us that the object of the book is primarily educational, and that it is in no sense intended as a work of reference; this object it fulfils admirably in most cases, but occasionally a few more references to literature would have been useful to the student who wished to acquire a fuller knowledge of a subject.

The subject-matter is treated under four divisions: (1) compounds with no nitrogen directly attached to carbon; (2) bodies containing one nitrogen atom attached to carbon; (3) compounds containing an open chain of two or more nitrogen atoms; and (4) ring compounds.

The first three divisions contain a much fuller and more detailed treatment of the subjects included in them than the fourth division, in which a few only of the more important cyclic compounds have been selected for discussion, and no mention is made of many groups, such as the pyrazolones or glyoxalines.

In chapter i. the nitrous and nitric esters are dealt with, while chapters ii. and iii. contain an excellent account of the amines.

Throughout the book the application of physical methods to the study of the problems of organic chemistry is continually brought to the notice of the reader, and the importance of the study of the mechanism of reactions and the quantitative side of the subject is emphasised: the latter is introduced by an excellent discussion on the strength of the amines as bases.

The constitution and reactions of the triphenylmethane dyes are treated very fully, but the account of the stereoisomerism of quinquevalent nitrogen compounds is not entirely satisfactory.

Chapter iv. contains an account of the amides, including a good discussion of the mechanism of the Hofmann reaction.

Derivations of hydroxylamine are dealt with in chapter v., in which the transformations of phenyl hydroxylamine are described very fully, and an admirable account of the isomerism of oximes is presented. The evidence for Hantzsch and Werner's hypothesis of stereoisomerism, culminating in the strongest argument yet adduced in its favour, namely, the resolution of oximino-cyclohexane carboxylic acid and into optically active components by Mills and Bain, is clearly expounded, but the statement that this theory is universally accepted is scarcely justified even now. A lucid account of the Beckmann transformation and its mechanism is also included in this chapter.

Chapters vi. and vii. deal with the nitroso- and nitro-compounds, and include a discussion of the constitution of the nitrophenols and their salts, the bearing of this on the problem of the relation of colour to constitution in these and similar substances, and also a very good account of the reduction of nitro-compounds and of the oxidation of amines.

The cyanogen compounds are described in chapter ix., in which the problem of the constitutions of hydrocyanic and fulminic acids and their salts occupies a prominent place. The evidence brought forward by Nef and other workers in support of the view that fulminic acid is the oxime of carbon monoxide seems now incontrovertible. None of the hypotheses suggested to account for the properties and reactions of hydrocyanic acid and the cyanides can be regarded as entirely satisfactory, but few will agree with the statement that "prussic acid is tautomeric, and is probably a mixture of two forms," since the same line of reasoning, as shown by Wade, would necessitate a similar assumption in the case of silver cyanide.

In division iii., chapter xi., which deals with the diazo-compounds, is the most interesting; here, however, we feel that the subject is not presented to the student in a way which makes him understand clearly the difficulties of the problem under discussion. Certain statements are put forward as if they were definitely established facts; whereas, on account of the experimental difficulties with which the problem is beset, the evidence on which some of these statements are based is not conclusive enough to justify one in accepting them without question. In the case of the diazo-compounds, the hypothesis of stereoisomerism does not rest on such a secure basis as in the case of the oximes, and it is still possible that the facts may be explicable on the basis of the structural laws without assuming stereoisomerism.

Uric acid and related compounds are treated briefly in chapter xv.

In division iv. the fatty diazo-compounds receive due attention, the pyridine and quinoline group are treated briefly, while coniine, piperine, and nicotine are the only alkaloids discussed.

A few errors, such as formaldehyde for formanilide (p. 82), and minerals instead of mineral acids (p. 209), were noticed, but we regret to find certain colloquial expressions, such as "A readily goes over into B," occurring so frequently; and the statement that a substance "can be broken up into two optically active forms," (p. 103), is hardly a correct or conventional description of the process.

The book contains excellent summaries of the present state of our knowledge on a large number of subjects, including many of the most controversial matters that have recently occupied the attention of chemists.

Usually the account of each subject will be found to include the most recent work of importance, though we notice the omission of the recent work on the mechanism of the transformation of chloroamines into chloroanilines.

Unfortunately the author often gives the impression that he treats a hypothesis or a theory as a fact, an attitude which we cannot regard as a desirable one for the student to adopt.

The student, for whom the book is intended, will find it will well repay careful study, and will discover in it much food for thought, while the author is to be congratulated on the production of a very useful work.

H. O. J.

SCIENCE AND HISTORY.

The Cambridge Modern History. Planned by the late Lord Acton. Vol. xii.: "The Latest Age." Pp. xxxiv+1033. (Cambridge: University Press, 1910.) Price 16*s*. net.

A COMPREHENSIVE and philosophical history of science in "The Latest Age" would be one of the most valuable and interesting works which it would be possible to produce, but it was not the purpose of the volume before us to produce it. Of its thousand pages only fifty have any special interest for students of science, the twenty-six pages of Mr. Whetham's chapter on "The Scientific Age" and the twenty-four pages of Mr. Rogers' "Modern Explorations." In so narrow a space it is not to be expected that there will be much that is novel or profound. Mr. Rogers can do little more than record a long list of names and dates; he cannot describe the effect upon modern civilisation of the discoveries without duplicating the work of other authors, to whom the reader is frequently referred. The present reviewer cannot express any judgment as to the accuracy or completeness of the list, but for these qualities the author's reputation is a sufficient guarantee. Mr. Whetham has rather more scope for comment, expressed with

the elegance which we expect from him; but even he can scarcely find room for any facts which are not familiar to every well-informed person, or any conclusions which are not the commonplaces of every journalist.

While nothing but praise can be given to the authors for the performance of their tasks, the decision of the editors that all the modern historian requires to know of the science of the last century can be contained in two short chapters seems at first to challenge criticism. But, so far as pure science is concerned, we believe that they are right. Pure science is the most esoteric of all studies; the power of appreciating the value of the ideas contained in the most fundamental scientific theories appears to be totally uncorrelated with any other form of mental ability. It is just because the scientific instinct is such a rare and peculiar gift that it is so intensely valuable. Even if it were possible for the mass of mankind to know truly the meaning of science, it is very doubtful whether it would have any effect upon those actions which history studies. Science cannot define a worthy aim for action; at most it can show what aims can be attained, not what ought to be attained. It was, of course, thought very widely forty years ago that what was "natural" was good, but the fallacy is quite exploded to-day. Indeed, it is probable that Spencerian sociology, based on the confusion of the biological and ethical meanings of the word "fit," would have never received any serious attention, had not the doctrine that what has survived ought to have survived been so comfortable to those in authority. All that the doctrine of evolution can teach us in the matter of aims is that man is master of his destiny, that it is neither sufficient nor necessary to wait for the dispensations of a mysterious providence, but neither the science of the last or of the next century will decide the eternally disputed question of what that destiny ought to be.

However, though pure science cannot give us ends, applied science can give us means, and in respect of applied science "The Cambridge Modern History" appears to us defective. There is no connected account whatsoever of the great inventions or the progress of engineering during "The Latest Age." Mr. Whetham, concerned with pure science, naturally only mentions discoveries which have been the by-products of pure research. We have bare references to photography, dynamos, telegraphy, and two pages concerning medicine, surgery, and hygiene. But many of the inventions which have had the greatest economic or historical effects have no immediate connection with pure science. Can the historian of to-morrow analyse the events of to-day if he has never heard of such things as telephones, explosion engines, modern armaments, water-power, or electric lighting? The most trivial invention in appearance may revolutionise the world. Mr. Whetham rightly says that "the locomotive engine and the electric telegraph effected the great industrial and social revolution of the middle of the nineteenth century"; we suggest that it would not be ridiculous to claim for an invention so uninteresting technically and scientifically as the bicycle a comparable influence upon the end of it. Besides its economic effect in increasing men's radius of action, its social effect in furthering the independence of women must surely make it worthy of the attention of a student of the modern state; and yet the editors of "The Cambridge Modern History" have no official knowledge of it.

THE THEORY OF FUNCTIONS.

Introduction à la théorie des fonctions d'une variable. By J. Tannery. Deuxième édition; tome 2. Intégrales définies, Développements en Série, Langage géométrique, Fonctions de Variables imaginaires. Avec une Note de M. Hadamard. Pp. iv+480. (Paris: A. Hermann et fils, 1910.) Price 15 francs.

THE most interesting chapter in this volume is that which is entitled "Langage géométrique," especially from a pedagogic point of view. The main object of the treatise is to deduce everything from purely arithmetical assumptions; but as a practical teacher, Prof. Tannery was well aware of the value of diagrams as an aid to the imagination, or, as he puts it, for purposes of orientation. Consequently he has given a series of quasi-geometrical definitions, by means of which the ordinary formulæ and methods of analytical geometry are valid, and may be used practically for constructing diagrams to define boundaries of aggregates, &c. In the ordinary sense, of course, we thus get a locus corresponding to an equation $\phi(x,y)=0$; but in order to emphasise the fact that only arithmetical conditions are really imposed, the author replaces the term "locus" (*lieu*) by "bond" (*lien*), and practically confines this to the case where we may put $x=\phi(t)$, $y=\psi(t)$, ϕ, ψ being definite functions for a certain range of the real continuous variable t. The principal results of the chapter are the proof of the existence of simple contours in a plane, which separate it into two distinct continua (this is given after Mr. Ames), and the further conclusion that a domain which is $(m+1)$ times connex can be reduced to two simply connex domains by drawing $(m+1)$ simple curves.

Another notion that occurs in this chapter is that of the order of a point A with regard to a closed contour C. If a point P traverses C once in the positive direction, the variation of the amplitude of the vector AP is of the form $2k\pi$, where k is some integer or zero; and k is called the order of A with respect to C. This very important idea was generalised by Kronecker, and the present volume concludes with an important note by M. Hadamard (pp. 437–77) on some applications of Kronecker's index. The main point of this theory is that the property of a Jacobian, that it changes sign when two rows are interchanged, is brought into connection with topology (or *analysis situs*) in a very general sense. Every advance in the analytical treatment of this subject is noteworthy; because it is here that the contrast between geometrical intuition and analytical proof is so often a glaring one. For example, take Minding's surface, which is obtained by taking a strip of paper, giving it a half-twist, and then pasting the free ends together. It is easy to see that this surface has only

one boundary and only one face, and that this property remains if the surface is "deformed" in the usual sense of that word. But it would be very troublesome to prove these facts analytically, and an ordinary person finds it hard to think of such a proof as being anything more than a superfluous *tour de force*.

Before leaving this chapter, attention may be directed to the use which is made of cuts (*coupures*) in the plane of reference. For certain purposes, as shown for instance by Hermite and Heine, it is more simple to use a plane with cuts in it than to construct a Riemann surface; and the beginner in function-theory may be recommended to master this method before proceeding to Riemann's.

The remaining chapters may be more briefly summarised. There is one on definite integrals introducing the indispensable notions of integrals by excess and defect, and functions of limited variation; one on development in series; two on complex variables and their functions; and one on the differentiation and integration of such functions. Very properly, the author has confined himself to well-known and comparatively simple functions as examples, and he has given figures to illustrate the conformal transformations effected by $\zeta = e^z$, $\zeta = \sin^{-1} z$, and so on. As incidental examples, we may mention the Eulerian functions, and Weierstrass's factorial formula for a function the zeros of which are given.

Mathematical teachers will doubtless find this work of great value, because it helps to suggest what is really practicable in a course of lectures on this subject. The fact is that the theory of aggregates, and the classification of functions, have become such an essential part of all analysis that they cannot be ignored. A serious mathematical student must understand what is meant by such terms as closed and open aggregates, limiting points, uniform convergence, &c., and know something of the conditions for differentiation and integration. But if, with excess of zeal, the lecturer tries to bring out every point, and to be impeccably logical, he runs a serious risk of boring his audience.

G. B. M.

PHYSIOLOGY OF REPRODUCTION.

The Physiology of Reproduction. By Dr. F. H. A. Marshall. Preface by Prof. E. A. Schäfer, F.R.S., and contributions by Dr. W. Cramer and Dr. J. Lochhead. Pp. xviii+706. (London: Longmans, Green, and Co., 1910.) Price 21s. net.

THE progress of science is very haphazard. For centuries the problems of breeding and heredity have engaged the attention of intelligent men, but it is only within the last five decades that any accurate scientific knowledge on the subject of breeding has been reached. Even now almost all our knowledge of this subject has been derived chiefly from a study of the results of the mating of two germ-cells. This one-sidedness is due to the processes which take place during reproduction being so little known.

This unequal advancement of the sciences is seen again in physiology. Here the physiology of digestion, of muscular contraction, of the nervous system, has been extensively studied, but that of reproduction has been largely neglected. Dr. Marshall has set himself to remedy this defect, and has collected all the available information on the subject. Reproduction incidentally concerns many different categories of people, and they have recorded their observations in numerous and varied periodicals and books. It must have been a task of considerable magnitude for the author to have collated all his sources of information; a glance at the references to quoted literature will convince us of this. The bibliography is in consequence not the least valuable part of the book.

But Dr. Marshall's volume is not merely a digested abstract of scattered papers taken from a great many journals; the author's own extensive work has given him an insight into his subject which enables him to impart information to his readers in a clear and lucid way. He has compiled a treatise which will remain a standard work for some time to come.

The work is to a great extent morphological, but, as everyone knows, it is absolutely necessary to have a sound knowledge of the structure of any organ before physiology is investigated. In studying such a process as the œstrus cycle, the exact morphological changes which take place in the uterus must first be known. This knowledge we owe to Heape, to whom we are glad to see the volume is dedicated, and it is the foundation of all our knowledge of the physiology of the œstrus cycle.

The author commences with a chapter on the breeding season of animals, examples being taken from invertebrates as well as vertebrates, but in subsequent chapters the higher mammalia are, with few exceptions, alone referred to. He then deals with the œstrus cycle and the changes which take place in both sexes both before and during reproduction. After this we have detailed all the evidence bearing on the changes in the maternal organs during pregnancy. The chapter on the biochemistry of the sexual organs seems only to show us how little we know, the information in it is so sparse and disconnected, and surely here is a valuable field for research. The last three chapters are on general questions of breeding, such problems as fertility and the determination of sex being dealt with.

Interspersed with the subject-matter we find the author's views on many theories as seen in the light of his own research. Thus, in the chapter on fertilisation, he gives a criticism of Mendelism. Close study of the actual physiology of reproduction does not lead the author to believe in the conception of unit characters, which the Mendelians have put forward. He speaks of the idea of attempting to locate latent characters of organisms in different parts of the germ-cell, as a survival from the times when all qualities, abstract or otherwise, were supposed to reside in different portions of the body. Whatever be the merits of this particular criticism, it seems that when further work has been done on the physiology of reproduction, a new mechanism may have to be supposed which will account for Mendelian facts, and fit in as well with the teachings of physiology.

Dr. Marshall has produced a masterly treatise

which gives us a very complete and critical review of all the facts of the physiology of reproduction. It will make a new "jumping-off place," as the Americans says, in research, and it is, moreover, admirably written. As an eminent gynæcologist said, "It is as interesting as a novel." It is a text-book which will be a great help to all those who are already working at the science, and a stimulus to encourage new workers. To everyone who is interested in breeding we would recommend this book, though it is not, however, in any sense a popular work.

SOUTH AFRICAN CRUSTACEA.

Annals of the South African Museum. Vol. vi., part iv., 6: *General Catalogue of South African Crustacea* (part v. of S.A. Crustacea, for the Marine Investigations in South Africa). By the Rev. T. R. R. Stebbing, F.R.S. Pp. 281–593, plates xv–xxii. (Cape Town: South African Museum; London: West, Newman, and Co., 1910.) Price 27*s*.

IN the study of the geographical distribution of marine animals, certain regions are of special significance from the fact that they lie on the borderlines between contrasted faunal areas, and offer, or may have offered in the past, possible routes of migration from one to the other. One of these critical regions is found at the Cape of Good Hope, where the faunas of the Atlantic, the Indo-Pacific, and the great southern oceans meet and, to some extent, overlap.

In recent years much information regarding the fauna of the Cape seas has been obtained in the course of investigations conducted under the superintendence of Dr. J. D. F. Gilchrist for the Cape Government, and published under the general title of "Marine Investigations in South Africa." To this series Mr. Stebbing has already contributed four important memoirs on the crustacea. In a fifth memoir, now published, he brings together the results of his own work and that of his predecessors who have dealt with this groups of animals, in a "General Catalogue of South African Crustacea," including the freshwater and terrestrial as well as the marine species.

In the present state of faunistic carcinology it is hardly possible to over-estimate the usefulness of such a catalogue, prepared, as it has been, with the thoroughness and detailed precision characteristic of all Mr. Stebbing's writings. Apart from the descriptions and figures of the numerous new and interesting species, the compilation of the bibliographical references alone must have involved a great amount of labour, of which subsequent students will reap the benefit. Although Mr. Stebbing touches only incidentally on geographical problems, his catalogue will provide a sure basis for future work on this subject.

As an example of the interesting points of detail contained in these memoirs, the case of the Cape lobster, *Homarus* (or, as Mr. Stebbing prefers to call it, *Astacus*) *capensis* may be mentioned. This pretty little species has been involved in obscurity since its first description in 1792 by Herbst, who stated that it lived in mountain streams at the Cape. H. Milne-Edwards later gave a brief description of the species, but added no information as to its habitat. Huxley, referring to it, says:—

"I must confess myself to be in a state of hopeless perplexity respecting the crayfish or lobster which is said to occur at the Cape of Good Hope."

Mr. Stebbing now supplies a full description of the species from specimens sent to him by Dr. Gilchrist, and finally disposes of the story as to its freshwater habitat. Like the other two species of the genus, the European and American lobsters of the north Atlantic, it lives in the sea, and its remoteness from the areas occupied by its congeners offers a noteworthy example of "discontinuous distribution." It may be mentioned in passing that the only figure of the Cape lobster referred to by Mr. Stebbing is the original one of Herbst, which is very inaccurate. An excellent figure was given by H. Milne-Edwards ("Ann. Sci. Nat., Zool." (3), xvi., 1851, plate xi., Fig. 1); but as it occurs among the illustrations of a morphological paper, it is easily overlooked.

Mr. Stebbing's use of the generic name *Astacus* for the Cape lobster affords an instance of the difficulties into which "reforms" of nomenclature may lead the unwary student. In this case the detailed synonymy which Mr. Stebbing gives prevents any ambiguity, but, unfortunately, other writers are not so careful, and, in view of the long-standing error as to its freshwater habitat, it may not be superfluous to warn the student of geographical distribution that "*Astacus capensis*" is *not* a crayfish.

In many other points of nomenclature the catalogue challenges criticism. Mr. Stebbing is well known as an uncompromising advocate of the strict rule of priority, but he is by no means ready to surrender the right of private judgment, and is even capable of treating disrespectfully the decisions of the International Commission on Zoological Nomenclature. At all events, whatever may be the case with genera and species, there is no law to compel, nor any perceptible advantage to recommend, a renaming of the accepted orders and subclasses of crustacea; and there can be little doubt as to the opinion of zoologists in general on the proposals to substitute Thyrostraca for Cirripedia and Ostrapoda for Ostracoda.

W. T. C.

SCIENCE FOR THE GENERAL READER.

Science in Modern Life. Prepared under the Editorship of Prof. J. R. Ainsworth Davis. Vol. v. Pp. ix+207. (London: The Gresham Publishing Company, 1910.) Price 6*s*. net.

THIS volume comprises four contributions, namely, by Prof. James Wilson on agriculture (32 pp.), by Dr. John Beard on philosophical biology (32 pp.), by Prof. Benjamin Moore on physiology and medicine (90 pp.), and by Dr. H. Spencer Harrison on anthropology (52 pp.).

The first article is almost entirely historical; it contains an account of the chief advances in British agriculture from Saxon times, but has little to say on present-day problems and researches. More space

might, with advantage, have been devoted to these subjects.

Dr. Beard gives, in his opening chapter, a concise statement of the views associated with the names of Lamarck, Spencer, Darwin and Wallace, and Weismann. The following chapter, on heredity, deals in turn with Galton's law, Weismann's theory of the germ plasm and with germinal continuity. The third chapter discusses Mendelism, biometry, and the mutation theory of De Vries. Dr. Beard's views can be best summarised by quoting the statement at the head of the concluding chapter—

"The phenomena of heredity and genetic variation appertain to the germ-cells, that is, they are germinal in nature. All ancestry passes through a continuous line of germ-cells, and never through the cells of the individual (somatic cells) containing the germ-cells. An 'inheritance of acquired characters' is impossible, for there is no handing on of anything. The individual is merely a terminal and lateral offshoot. In the higher animals direct development, a building up of the individual, and a somatic origin of germ-cells, do not exist. . . . The formation of an individual is a mere incident in a certain chain of events."

He concludes by stating his belief that unconscious memory, in Hering's sense, is sufficient to account for heredity as exhibited by living things, and that if this be recognised "much that has been imagined becomes, not merely futile, but an unnecessary multiplication of causes."

Prof. Moore has given an interesting account of the functions of many of the different kinds of cells of the body, for instance, the leucocytes, the red blood-cells and their adaptation of form to their special functions, the intestinal cells and their secretion, the ductless glands and internal secretions, &c. Clearly written explanations, as free from technicalities as possible, are given of many of the new terms used in modern medical science, *e.g.* agglutinins, anti-bodies, opsonins, precipitins, antisera, hormones, &c.

The chapter on tropical diseases is much too short. The only diseases considered are malaria and sleeping sickness, and the account of the former contains a considerable number of imperfect or inaccurate statements. The following occur on one page (144) (1): "The mosquito was found to develop a special cycle of the malarial parasite in the glands of the stomach," which is a very loose statement of the matter; nothing is said of the presence of the parasites in the salivary glands of the mosquito, or of their mode of entry into a new human host. (2) The changes in the organism of malaria which take place in the mosquito are designated "certain preliminary stages of development," which surely gives but a faint idea of the fundamental changes which actually occur. (3) Mosquitoes do not deposit larvæ, as asserted, but lay eggs. (4) It is stated that the larvæ, "in order to develop further, must at a certain period ascend to the air at the surface of the water"; as a matter of fact they must ascend periodically, and in most cases frequently, in order to obtain the necessary air. Laveran is not Italian, as stated on p. 143, and the first trypanosome in a European was described by Dutton, not Dalton (p. 145). We should have thought that the recent campaigns against Stegomyia (not Stegomya, p. 144) and yellow fever were worthy of more than casual mention, and that several other tropical diseases were of sufficient general interest to make reference to them desirable. Figures of Anopheles and a tsetse-fly would have been helpful to the reader.

In the short chapter on public health, the author shows how the general health of the community has improved, and urges the necessity for segregation of, and vigilance regarding, cases of consumption.

Dr. Harrison outlines in an interesting manner the chief phases of development of anthropology; the origin of man, of inventions, of civilisation, and of the races of man, are discussed, and an account is given of the races of Europe and of Britain. The article is illustrated by several excellent photographs and a number of coloured and line drawings.

OUR BOOK SHELF.

The Niger and the West Sudan, or the West African's Notebook. A Vade Mecum containing Hints and Suggestions as to what is Required by Britons in West Africa, together with Historical and Anthropological Notes, and Easy Hausa Phrases Used in Everyday Conversation. By Captain A. J. N. Tremearne. Pp. viii+151. (London: Hodder and Stoughton, and A. H. Wheeler and Co., n.d.) Price 6*s.* net.

THIS book is written by a former Hausa scholar of Cambridge, who is also a doctor in anthropology, and the work is the result, seemingly, of some years' residence in Nigeria, with visits to the British colonies *en route*. It contains a good many vocabularies of English-Hausa interspersed amongst the chapters, and some of these will no doubt be of much use to officials and travellers residing in or visiting these regions. There is a great deal of general information about British West Africa, but little evidence of independent research on the part of the author, while the quotations with which the book is studded are of a somewhat ancient and well-worn character. Some recent French and German works (historical, geographical, anthropological, &c.) are overlooked, though they throw a new light on the ancient history of British possessions in West Africa, as well as of the adjacent regions under other flags.

A somewhat contemptuous attitude is taken up with regard to the educated negro, which seems to be derived less from the author's own observation and experience than from the pessimistic views expressed by writers and travellers of half or a quarter of a century ago. In reference to the youth trained at Government or missionary schools—in Sierra Leone, for example—the author seems to be quite unaware of the part played by these intelligent and active young men—engineers, artisans, clerks, &c.—in the opening up of the interior of that colony, or in like manner of the Gold Coast.

In drawing up a list of societies and institutions which may be of use to the African official or student, the writer of this book omits all mention of the African Society, which is surely one of the most useful, for its journal contains the best and latest information on West African subjects. The portion of the work which deals with the Hausa people (chiefly by quotations) possesses some interest, but contains fantastical notions, original and borrowed, which may only mislead the student, such as, for example, the suggested derivation of Hausa from Habeshi

(Abyssinian). Nevertheless the book under review sums up in small compass much of the interest of northern Nigeria.

Lehrbuch der allgemeinen Pflanzengeographie, nach entwickelungs-geschichtlichen und physiologisch-ökologischen Gesichtspunkten. Bearbeitet von Prof. P. Graebner. Mit beiträgen von Prof. P. Ascherson. Pp. viii+303. (Leipzig: Quelle and Meyer, 1910.) Price 8 marks.

No branch of botany has advanced more rapidly in the last quarter of a century than the study of plant geography or distribution. Although the foundations were laid by Humboldt (1805), de Candolle (1855), and Grisebach (1872), much of the impetus is due to the influence of the already classical works of Warming and Schimper, and to the valuable contributions by Dr. Engler; further, the numerous recent papers devoted to the descriptions of vegetation in all parts of the world have provided additional data for establishing general principles.

Plant geography presents the two main aspects of distribution in space and distribution in time. The former has received more attention, and provides the sole topic of most books on the subject. Dr. Graebner has devoted a third part of his book to an account of development in past geological ages and in historical times. This provides a serviceable epitome, although some of the statements—as, for instance, the suggested aquatic habit of the Sphenophyllaceæ—are questionable. The discussion of events in the Tertiary and Glacial periods leads up to such matters as plant migrations, centres of distribution, origin of new species, variation, casuals, aliens, and colonists. Distribution in space is taken in two sections, of which the first relates to floristic kingdoms, the second to ecological conceptions. The consideration of the subject from these two points of view would serve a useful purpose if the advantage was not discounted by the excessive condensation necessitated. The description of causes influencing plant distribution in the present day contains a store of details gleaned from scattered papers, and provides much material for elaboration. Very little space is apportioned to the account of plant formations; their classification is based upon the paucity or richness of the available food supply in the soil. Numerous references to original publications are supplied in the footnotes, which it would seem worth while to collect into an appended classified bibliography.

The Natural History of Coal. By E. A. Newell Arber. Pp. x+163. (Cambridge: University Press, 1911.) Price 1*s*. net.

Within the narrow compass of this little volume, which forms one of "The Cambridge Manuals of Science and Literature," Mr. Newell Arber has condensed a great amount of solid information with respect to the nature of coal, and much speculation with regard to its probable mode of formation. Perhaps the most notable feature of the work is the emphasis which it lays on the fact that "coal" is merely a group-name, applied popularly to a number of carbonaceous substances, very varied in character and doubtless very diverse in origin. No one mode of formation is applicable to all coal. If it can be proved in a particular case that the vegetation from which the coal was originally formed must have grown on the spot where it is now found, we are by no means justified in denying that in other cases the vegetable *débris* may have been drifted to its present site.

The author holds that each group of coal-bearing rocks, even each seam of coal, must be studied and judged on its own merits. The material from which coal has been formed he calls "the mother-substance of coal"—an expression not to be confused with the term "mother of coal," which has long been applied, perhaps not very appropriately, to the substance known otherwise as mineral charcoal. Mr. Arber discusses, with much command of his subject, the character of the coal-forming vegetation, the mode in which its relics accumulated, and the changes to which they have been subjected in the process of coal-making.

The view which regards the formation of palæozoic coal as having been comparatively rapid finds favour with the author, whilst doubt is thrown on the popular "peat-to-anthracite theory." As to the vexed question of the climate of Upper Carboniferous times, Mr. Arber hesitates, for apparently good reason, to term it tropical.

Eine Botanische Tropenreise. Indo-Malayische Vegetationsbilder und Reiseskizzen. By Prof. G. Haberlandt. Zweite Auflage. Pp. viii+296. (Leipzig: W. Engelmann, 1910.) Price 11.60 marks.

There is very little change to note in the present edition of Haberlandt's "Botanische Tropenreise" as compared with the original that was published in 1893. A few paragraphs have been inserted here and there, some excellent reproductions from photographs have been added, and three coloured reproductions from water-colour sketches by the author. It would have been unwise to reconstruct the general text, which records the fresh impressions of a first visit to the tropics. The chapters on tropical leaves and trees, lianes, epiphytes, and mangroves are specially instructive, and the bold pencil sketches delineate characters which are not discernible in a photograph.

Star People. By Katharine Fay Dewey. With illustration by Frances B. Comstock. Pp. x+232. (London: Longmans, Green, and Co., 1910.) Price 6*s*. net.

Some of the mythological characters which figure among the constellations are here introduced into a fantastic story. We cannot believe that the original legends have been improved by their setting, or that there is anything particularly inspiring in the association of stars with nonsense talk and a giggling company. Draco is afflicted with a lisp, and is made to say on one occasion "That'th all right. I gueth I can walk with three girlth. I'm long enough!" The constellations are so beautiful and the dramas they represent are so rich in imaginative ideas that we should prefer not to introduce children to either through a story of this kind, which can scarcely be regarded as good literature and is certainly not good science.

With Nature and a Camera: Being the Adventures and Observations of a Field Naturalist and an Animal Photographer. By Richard Kearton. Illustrated by 180 pictures from photographs by Cherry Kearton. Popular edition. Pp. xvi+368. (London: Cassell and Co., Ltd., 1911.) Price 5*s*.

Its re-issue in a cheaper form should increase the already wide popularity of this attractive book. The character of the work was described in Nature soon after its appearance (vol. lvii., p. 154).

British Birds in Their Haunts. By the late Rev. C. A. Johns. Twelfth edition, with 16 coloured plates. Pp. xxxii+626. (London: Society for Promoting Christian Knowledge, 1911.) Price 5*s*.

A book which has reached its twelfth edition needs no commendation. It is evident that its clearly expressed descriptions have proved of real assistance to students of bird-life.

Das Wasser. By Dr. O. Anselmino. Pp. vi+122. (Leipzig: B. G. Teubner.) Price 1.25 marks.

THIS booklet is the 291st volume of a popular scientific and literary series. It embodies the material used in a course of experimental lectures given at Griefswald in 1907. The subjects dealt with include the chemistry of water, mineral waters, the purification of water, drinking water, mineral waters, and diffusion. The text is illustrated by forty-four diagrams, most of which have been taken from text-books of chemistry, to which due acknowledgment is made. The author has brought together a large array of facts, the tabulated analyses of various waters, including a long series of mineral waters, being a conspicuous feature of the book. The chapter of chemistry covered by the title is an important one, and it is probable that its treatment in a separate volume may prove to be a convenience to a considerable class of readers.

What Nature Is. An Outline of Scientific Naturalism. By Chas. K. Franklin. Pp. iv+74. (Boston: Sherman, French and Co., 1911.) Price $0.75 net.

A WELL-WRITTEN argument for "scientific naturalism" as against the argument from design, which sees intelligence in nature, inferring therefrom a creator. Mr. Franklin rejects anthropomorphic theism, also idealism, but seems to finish up in a kind of mysticism. "It is the character and quality of matter and energy to develop" man and the social process, just as it is for them to manifest themselves in the inorganic and organic processes. New thoughts, feelings, volitions, religion, &c., are merely manifestations of "radiant and gravitant energy." But somehow we shall eventually "be able to comprehend what the universe is, conceive infinite time and infinite space by looking in upon ourselves and seeing the infinite repeated in us, and understand the inmost nature of things. Just as the time was when life was not self-conscious, then became self-conscious and class-conscious, and to-day is imperfectly socially conscious; and so the time will come when we shall be universally conscious" (pp. 71–72).

Perhaps so; it is interesting as a speculation, and the author has probably been reading Dr. Bucke's "Cosmic Consciousness." But Mr. Franklin is rather dogmatic, and is a little apt to slide into speculation suddenly after writing a good deal of sensible science; the reader therefore has to keep an eye on him, and to guard against too hasty following. Moreover, the reduction of everything to "energy" does not in the least resolve the ultimate mystery of things, as Tyndall, for instance, saw plainly enough.

Morale de la Nature. By M. Deshumbert. Second edition. Pp. 96. (Paris: Schleicher Frères, 1911.) Price 1.50 francs.

WE have here the second French edition of a book which, since its first appearance, has been translated into English by M. I. M. Hartmann, and published by Mr. D. Nutt, under the title, "The Ethics of Nature." The original work led to the formation of the "Ethics of Nature Society," which is an association for the harmonious development of life. The present edition of M. Deshumbert's book has been revised and enlarged.

Carnations and Pinks. By T. H. Cook, J. Douglas, and J. F. McLeod. With eight coloured plates. Pp. xi+116. (London: T. C. and E. C. Jack, n.d.) Price 1s. 6d. net.

THE latest addition to the "Present-Day Gardening" series will be welcomed by all active horticulturists. Being the work of expert cultivators of the flowers with which it deals, the volume should soon become widely known and consulted on account of the practical hints it contains.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

Stability of Aëroplanes.

THE following simplification of Lanchester's formula for longitudinal stability of tailed monoplanes may be useful.

His formula is

$$\Phi = \frac{4l\mathrm{H}_n^2 \tan\gamma}{\mathrm{I}\left(\frac{1}{\mathrm{K}} + \frac{1}{c\mathrm{C}\rho\epsilon\alpha\beta}\right)}.$$

("Aërodonetics" ρ 101).

Here H_n is the height corresponding to the normal velocity of the machine $= \mathrm{V}_n^2/2g$ and $\mathrm{I} = \mathrm{WR}^2$ where R is the radius of gyration about a transverse axis through the centre of gravity, and K is $g\mathrm{W}/\mathrm{V}_n^2$, where W is the mass in pounds.

$c = 3{\cdot}0$, $\mathrm{C} = 0{\cdot}7$, $\rho = 0{\cdot}08$ pounds per cubic foot, $\epsilon =$ about $0{\cdot}6$ for tails of moderately high aspect ratio, so that $c\mathrm{C}\rho\epsilon = 0{\cdot}1$ nearly.

Hence

$$\Phi = \frac{l\mathrm{V}_n^4 \tan\gamma}{g^2\mathrm{R}^2\left(\frac{\mathrm{V}_n^2}{g} + \frac{10\mathrm{W}}{\alpha\beta}\right)}.$$

(See "Problem of Flight," 2nd edition, p. 114.)

For most machines with pterygoid aërofoils of approved camber γ and β are about $\frac{1}{6}$ radian.

Further the value of W (pounds not poundals) is connected to the supporting area by approximately the equation $\mathrm{W} = 0{\cdot}0016\ \mathrm{AV}^2$ so that $\mathrm{V} = 20$ to $30\sqrt{(\mathrm{W/A})}$, or say $30\sqrt{w}$, where w is the lift in pounds per sq. foot.

Hence approximately

$$\Phi = \frac{l \times 30^4 \times w^2 \times \frac{1}{6}}{1024\mathrm{R}^2\left(\frac{30\sqrt{w}}{32} + \frac{10\mathrm{W}}{a \times \frac{1}{6}}\right)}$$

taking $\Phi = 1{\cdot}5$ and writing $\mathrm{W} = w\mathrm{A}$, we get very nearly

$$l = \frac{\mathrm{R}^2}{500}\left(w^{-\frac{3}{2}} + 60w^{-1}\frac{\mathrm{A}}{a}\right)$$

thus expressing the length of the tail in terms of the radius of gyration, the loading per sq. foot, and the ratio of the supporting area to the tail area.

For example, if $\frac{\mathrm{A}}{a} = 10$, and $w = 2$ lbs. per sq. foot,

$$l = \frac{\mathrm{R}^2}{500}\left(0{\cdot}35 + 300\right) \text{ or roughly } \tfrac{3}{5}\mathrm{R}^2.$$

Thus a machine the radius of gyration of which is 7 feet, loading 2lbs. per sq. foot, and having 10 per cent. tail area, needs a tail with $\frac{3}{5} \times 7^2$, say 30 feet radius of action (*cf.* Bleriot machine).

The Daintiness of the Rat.

ONE of the principal sights in Bordighera is the garden of the Villa "Charles Garnier." It is called after its late owner, the famous designer of the Grand Opera at Paris and the Casino at Monte Carlo. It was probably when he was engaged in building the Casino that he acquired the large and valuable property which bears his name.

The garden covers more than five acres, and is a mass of tropical and subtropical vegetation. The banana trees bear fruit which ripens every year. The gardener, a very civil and intelligent man, speaks English, and he told me he had worked for more than a year in Kew Gardens, which he much admires, and endeavours to imitate when his means permit. He was especially proud of his ticketing the plants after the Kew model.

Not being a botanist, I was unable to appreciate adequately his attention in showing me the treasures of his garden, and it was perhaps owing to his perceiving

this that he directed my attention to an allied circumstance which interested me much.

He informed me that the greatest trouble which he had was with rats, the *forest rats* he called them. They spend the winter in the garden, and, while causing a good deal of general damage, they evince a remarkable selectiveness in their taste for fruit. It appears that they have a great preference for the lemon and the mandarin, which are abundant in the garden. A number of the trees carried zinc guards on their trunks to prevent the ascent of the rats; but in a terraced garden on a steep slope there are many which cannot be protected in this way, because a rat easily jumps from a higher terrace on to the upper branches of a tree growing on the terrace below. By this means they had boarded and plundered quite a number of trees. They touched only the lemon and the mandarin trees, disregarding the common orange. But what seemed to be most remarkable was the different way in which they treated the fruits of these two trees. Of the lemon they eat the rind, removing it completely, and leaving the peeled fruit, clean and without a blemish, still attached to the branch which carried it. On one tree there were eight or ten such freshly peeled lemons still in their places on the tree, and they presented, among the others, a very curious aspect of nakedness. Having boarded a mandarin tree, the rat treats the fruit in the opposite way; he eats the inside and leaves the empty skins hanging on the tree. On one tree that I saw, nearly the whole of the fruit had been treated in this way. Something similar may be witnessed with us on gooseberry bushes in a summer when wasps are abundant. The reason for the different treatment of the two fruits is probably not to be sought further than in the fact that the inside of the mandarin is sweet and that of the lemon sour.

So long as there are mandarins and lemons, the common orange remains untouched, but when there are no more of these two they eat the common orange. By the time these are finished the fields and woods outside are beginning to furnish food, and the rats leave the garden, not to return until the winter begins again.

In answer to my inquiry, the gardener said the rats never attempt to enter the villa; they are forest rats. I asked him if they were a special kind; he said they were brown rats; and I asked him if they were different from the rats he had seen in England, and he said no.

The daintiness of the rat, shown not only in the choice of his fruit, but also in the part of it which he will eat, is not the only feature of rat life which is illuminated by the experience of the gardener of the Villa "Charles Garnier." The annual migration back and forward from the open and natural surroundings of the field and forest, where in summer food is being naturally produced in abundance, to the restricted environment of the highly cultivated garden, where in winter food is produced only by artificial devices, becomes more remarkable the longer it is contemplated. The whole area of semi-tropical garden on the Riviera is an insignificant quantity compared with that of the open ground, so that the proportion of the rat population which is able to enjoy the winter *villegiatura* must be very small, and must be chosen or evolved by a rigorous system of selection, which probably rests on the fundamental principle, the right of might.

In a fertile country like that of Liguria the rats, which are obliged to remain *fore le muri*, are no doubt able to pick up a subsistence during the winter, but they cannot afford to be so dainty as those that are able or privileged to occupy the gardens. In any case, I suppose, it may be taken to be true that a hungry rat will not hesitate to eat a healthy brother rat if he can waylay him or overcome him in combat. It is not improbable that this is the natural winter food of many tribes of rats which inhabit countries where food has its seasons of plenty and scarcity. The shortage thus produced in the winter is quickly made up by the splendid fruitfulness of the mother rats when the food season returns, and the population, over the year, need show no diminution; indeed, there is nothing to prevent it showing an increase. In nature there are accumulators of all kinds.

We have seen, on the evidence of the fruit trees of the garden, that the rats occupying it must live in that state of luxury in which the sensation of real hunger is not felt. How do they keep such a garden of Eden to themselves?

That the common oranges remain as a reserve to the end of the season shows that overcrowding is effectively prevented. We have seen that the lemon and the mandarin are preferred by the rats actually occupying the garden, and apparently indifferently, because the two fruits are consumed *pari passu*. As it is contrary to the animal nature for the strong to give way to the weak, we may feel certain that there is no relative aversion to either the lemon or the mandarin as there is to the common orange, or one of them would be consumed before the other.

All these facts go to show that the occupying force must be a very well-organised body, and must be directed by that degree of intelligence which teaches it, not only to drive and keep out strangers, but also rigorously to keep down its own numbers to the point at which it can, on the basis of experience, expect to pass the winter without being reduced to the necessity of eating common oranges.

Bordighera, March 20.

J. Y. Buchanan.

The Fox and the Goose.

The interesting story concerning a fox and its fleas related by Prof. McKenny Hughes recalls one told me many years ago by an old gamekeeper on Lord Ilchester's estate at Redlynch, in Somerset. The park at Redlynch is enclosed with a rough wall about 5 feet high; the keeper's cottage is in the line of this wall.

He saw one day, whilst sitting in one of his rooms, a fox coming towards the wall carrying a goose, which it had slung over its shoulders and was holding by the neck. Upon reaching the wall it tried to jump or clamber upon it, but failed. It repeated the attempt two or three times, going back a little distance and readjusting its burden each time before doing so. Finding that it could not get over in this way, it stood on its hind legs with its front feet against the wall, and, holding the goose by the neck close to the head, pushed the bill into a crack between the stones. The goose fell down, the crack being apparently too wide. A second attempt was successful, and the bird dangled from the wall suspended by the bill at almost 4 feet from the ground. The fox then leapt upon the wall, and leaning over withdrew the bill from the chink, hoisted up the bird, and disappeared with it on the other side.

The Rusting of Iron.

In an article in Nature of March 2 on the rusting of iron, an objection was raised to the work of Lambert and Thomson (Trans. Chem. Soc., 1910) on the ground that their experiments were carried out in fused quartz vessels. The writer of the article puts forward the view that fused quartz dissolves in water to produce silicic acid; that the acid produced is sufficient to dissolve the iron; that enough iron will be dissolved by the process in the course of a few hours to produce, in the presence of pure oxygen, a visible quantity of ferric oxide! He cannot have supposed that the *probability* which he discusses was not considered by the authors. The object of the work was to bring together iron, oxygen, and water, all of the highest obtainable purity, and to let them react in vessels which would be least likely to affect the reaction.

It was only after most careful experiments on the suitability of quartz vessels that they were finally chosen. A long series of experiments, lasting over several months, was carried out, in which (1) fused quartz vessels, carefully cleaned, as described in the paper, (2) fused quartz vessels lined with purified paraffin wax, (3) Jena glass vessels lined with purified paraffin wax, were used under exactly the same conditions.

The experiments were carried out as described in the paper. The apparatus was evacuated down to 0·0001 millimetre (as measured by a McLeod gauge); water was distilled in from a solution of pure baryta, the conditions being such that the water which came in contact with the

iron could only have condensed on the inside of the tube in which the metal was contained.

Oxygen, made by electrolysis of pure baryta solution, was finally allowed to enter the vessels. The paraffin wax used to line the quartz and glass vessels was purified by boiling with many changes of "conductivity" water, with frequent shaking, for about 100 hours. The iron used was a commercial electrolytic sheet iron containing 99·9 per cent. iron. It was carefully cleaned with finely divided carborundum.

The results were the same in the quartz vessels and in the quartz and glass vessels lined with paraffin wax. Rusting was visible in all cases within a few hours.

It was only when pure iron, made as described in the paper, was used that no rusting took place.

After these and other experiments, it was considered that quartz vessels, which lend themselves admirably to cleaning and purification, were the most suitable vessels in which to study the reaction.

It is claimed by the authors that they have established the following facts:—(1) Pure iron does not rust when placed in contact with pure water and pure oxygen. (The term pure is used, of course, in a relative sense.) (2) The contention that "the *dominant* factor in the atmospheric corrosion of commercial iron is carbonic acid," or any other acid, is untrue. This must not be taken to mean, however, that carbonic acid plays no part in the atmospheric corrosion of ordinary commercial iron.

Bertram Lambert.
Chemical Department, University Museum, Oxford.

The reference made to Mr. Lambert's work in my note on the rusting of iron has already proved of value in eliciting from the author a statement in reference to tests carried out in vessels lined with purified paraffin wax. His statement does not, however, provide a solution of the problem to which attention was directed, namely, that commercial iron exposed freely to air and water under the conditions described by Moody and by Friend does not rust, whereas in his own experiments rusting took place in the case of all but the most highly purified samples. It is difficult to predict whether the essential difference which still awaits discovery will ultimately be found in the iron, in the air, in the water, or in the vessel, but it is to be hoped that further discussion—in the columns of Nature or elsewhere—may speedily throw light on this difficult and important matter.

It is a common experience, of which Mr. Lambert's work has provided excellent illustrations, that an unsuspected impurity (such as platinum in iron) is far more likely to promote than to prevent chemical change. It was for this reason that attention was directed first to the experiments in which rusting actually took place rather than to those in which it was successfully prevented. My suggestion in reference to silicic acid is correctly described, but I do not think that a note of exclamation was called for in view of the fact that mere contact with glass, as Moody found, actually produces the effects referred to, not in oxygen, but in purified air. The quantity of acid required to initiate the rusting must be extremely small, but its complete removal seems to outweigh in importance every other factor that may be taken into consideration. This view is amply supported by the fact that Friend, using common iron, common air, and the simplest apparatus, was able to stop the rusting by the simple device of washing the iron with a common alkali and then rinsing it with common water evaporated from the alkali and condensed on the iron.

With the first of Mr. Lambert's claims I am entirely in agreement; his second claim I regard as unproved and fallacious. To the statement that "the dominant factor in the atmospheric corrosion of commercial iron is carbonic acid" I adhere unreservedly, not only because the corrosion can be stopped by the addition of an alkali or by the removal of acid, but even more emphatically because the carbonic acid leaves behind an irrefutable proof of its activity in the presence of something like 10 per cent. of ferrous carbonate in the rust formed under the commonplace conditions to which I referred. T. M. L.

April Meteors.

The following are the most important meteoric events that become due from about April 6 to April 30 in the present year:—

Epoch April 5, 21h. (G.M.T.), approximately second order of magnitude. Principal maximum April 6, 21h. 55m.; secondary maximum April 6, 1h.

Epoch April 7, 17h, eighteenth order of magnitude. Principal maximum April 9, 9h. 40m.; secondary maxima April 8, 2h. 15m., April 8, 11h. 30m., and April 9, 21h. 30m.

Epoch April 10, 17h., twenty-third order of magnitude. Principal maximum April 9, 0h. 15m.; secondary maxima April 8, 21h. 15m. and April 10, 14h. 30m.

Epoch April 11, 4h., twenty-eighth order of magnitude. Principal maximum April 11, 11h. 15m.; secondary maximum April 12, 7h. 15m.

Epoch April 13, 22h. 30m., thirty-third order of magnitude. Principal maximum April 14, 15h. 40m.; secondary maximum April 15, 14h. 40m.

Epoch April 17, 17h., twenty-ninth order of magnitude. Principal maximum April 18, 2h. 15m.; secondary maximum April 18, 4h. 50m.

Epoch April 19, 8h., twenty-fourth order of magnitude. Principal maximum April 17, 13h. 40m.; secondary maximum April 17, 21h. 45m.

Lyrid epoch April 19, 14h. 30m., approximately eighth order of magnitude. Principal maxima April 17, 20h. 50m., and April 19, 9h. 50m.; secondary maxima April 19, 9h. 30m., and April 19, 11h. 40m.

Epoch April 23, 3h. 10m., approximately sixth order of magnitude. Principal maximum April 21, 16h. 40m.; secondary maxima April 21, 3h. 55m., and April 22, 20h. 30m.

Epoch April 25, 6h. 30m., eleventh order of magnitude. Principal maximum April 23, 13h.; secondary maxima April 23, 23h. 30m., and April 24, 22h. 50m.

Epoch April 26, 6h., thirty-first order of magnitude. Principal maximum April 27, 12h. 10m.; secondary maximum April 27, 4h. 40m.

Epoch April 27, 1h., approximately tenth order of magnitude. Principal maximum April 28, 22h. 50m.; secondary maximum April 27, 23h. 50m.

Shooting stars should be numerous on April 19, as several maxima occur shortly before midnight on this date, among which Lyrids and bright meteors from allied radiants will probably be strongly in evidence. There is also another Lyrid display on the night of April 21, but it will only be partially visible on this side of the Atlantic.

April 3. John R. Henry.

Insurance against Rain.

As this scheme of insurance is one of the few of which data can be obtained by "the man in the street" from which the odds in favour of the underwriters can be calculated, I went to the trouble of investigating the matter. Possibly the results may interest your readers.

In "British Rainfall" for 1909, by Dr. Hugh Robert Mill, statistics are given of the number of days on which varying quantities of rain fell. The figures give the average for thirty-seven rainfall stations in England and Wales over a period of seven years, 1903–9. From these, by a method of interpolation, it is found that fifty-eight days in a year may be expected to show a fall of 0·20 of an inch or more, and seventy-four of 0·15 or more.

Working out the probabilities on the basis of these figures, assuming that rain on one day is independent of rain on any other day, the following results are obtained:—for every 100*l.* received in premiums the underwriters may expect to have to pay, in the case of Policy A, 66*l.*; Policy B, 74*l.*; Policy C, 43*l.*; and Policy D, 64*l.*

In favour of the underwriters is the fact that in the south and south-east, where alone the scheme is applicable, the probability of rain is less than in England and Wales generally. A further point in their favour is that the summer months are less wet than the mean of the whole year on which the above figures are calculated.

C. O. Bartrum.

The Use by Men of Science of an Artificial Language.

In Nature of March 30 (p. 155) the remark is made that "if it were possible to arrive at a general agreement [as to the use of an artificial language], even in one or two isolated sciences only, a real step in the diffusion of science would be made."

I desire to protest strongly against this view. Is it in the least likely that those Italians, Spaniards, Russians, Poles, &c., who will not now write their scientific papers in English, French, or German would write them in an artificial language? If they did so, while making themselves understood by a few *esperantists* or *idoists*, they would render themselves unintelligible to their own countrymen and all the rest of the world.

Science is sufficiently unattractive to the layman without being handicapped by an artificial language. Surely it is not too much to expect Poles and others to learn one of the three great modern languages—English, French, or German.

What is required is some organisation by which all important papers not published in English, French, or German shall be translated into one of those languages if it is found impracticable to *induce* the writers originally to publish them in one of the three great languages.

Bernard Hobson.

Thornton, Hallamgate Road, Sheffield, March 31.

A Wave Theory of Gravitation.

In the paper by Mr. C. F. Brush on a kinetic theory of gravitation, published in a recent number of Nature, a theory is suggested in which gravitational attraction is attributed to radiation pressure on the outsides of two gravitating bodies, so that "attraction" is rather a push than a pull. In fact, in outline the theory may be compared to Le Sage's corpuscular theory, in which the impinging atoms are replaced by a special type of æther wave exerting a pressure. That view is not altogether new.

I published an article in *The New Ireland Review* for August, 1907, in which that view was suggested as a speculation. Mr. Brush's theory differs in some of its details from the view I proposed, as, for example, the origin of the radiations. This view was suggested by Prof. Poynting's experiments on the "pressure of light." In my paper no mention is made of a very similar suggestion made some years earlier by Sir J. J. Thomson in a lecture delivered in Yale University in 1903, and afterwards published under the title of "Electricity and Matter." At the time of writing the article referred to I had not become acquainted with Prof. Thomson's suggestion. On p. 160 of the work just mentioned we read:—"We have seen in the first chapter that waves of electric and magnetic force possess momentum in their direction of propagation; we might therefore replace Le Sage's corpuscles by very penetrating Röntgen rays." The difficulties in the way of such a view are also indicated.

H. V. Gill.

Belvedere College, Dublin.

An occurrence of the Barium-felspar Celsian in North Wales.

Some finely crystallised mineral specimens from North Wales, kindly sent to me by Mr. G. J. Williams, H.M. Inspector of Mines, have proved on a preliminary examination to be the rare mineral celsian, hitherto recorded only from Sweden (by H. J. Sjögren in 1895). The beautifully developed monoclinic crystals are colourless and transparent, and extremely rich in faces. They are accompanied by other crystals of orthorhombic habit, which possibly represent a dimorphous form of barium-felspar. I am at present engaged on a chemical analysis of these crystals, and Mr. L. J. Spencer has undertaken to determine their crystalline form and optical properties.

Arthur Russell.

Swallowfield Park, Reading, March 27.

AN INTERNATIONAL VULCANOLOGICAL INSTITUTE.

At the International Geological Congress held last year in Stockholm, Signor Immanuel Friedlaender proposed the foundation of an Institute for Vulcanological inquiries. The matter was submitted to a commission which reported on it to a general meeting of the congress in a highly favourable manner. The object of the institute is to carry out continuously and systematically researches connected with volcanic phenomena. It is proposed to build a laboratory furnished with instruments for the measurement of the temperature of rocks and of gas at different points of Vesuvius; to analyse the gas from *fumaroles*, and to note seismic disturbances.

The existence of the present observatory at Vesuvius is known throughout all the world, but unfortunately at it continuous systematic researches have not been carried out, neither have they been carried out at any other volcano in the world. Thoroughly to accomplish what is proposed it is necessary to have an international union, not only for the purpose of collecting the necessary monies, but also to furnish the opportunity to men of science of all nations to make investigations at the new institute. The number of vulcanologists in Italy and in other parts of the world is few, a matter that can be easily understood, because there does not exist any permanent positions for specialists in this subject. The scientific importance of the undertaking does not require discussion. It has, however, a practical aspect. The enormous damage and loss of life by the eruptions of Krakatoa, Monte Pelée, and of Vesuvius in 1906, are fresh in our memory. Our present knowledge of volcanic phenomena is based upon intermittent observations, and therefore it is not sufficient to enable us to predict eruptions. Notwithstanding this, we now know that vulcanicity shows a series of regular phenomena. From this it appears that it is not only possible, but it is highly probable that after conscientious and exact registration of all the phenomena, science will shortly advance so far as to foresee more or less the time of occurrence of a new outburst. There exists another practical reason why we should study vulcanology. By the study of the activity of *fumaroles* and the metamorphosis of rocks, we may explain the origin of many minerals. Recent volcanoes are known to contain metalliferous minerals in course of formation, and a profound study of the phenomena of metamorphosis would therefore greatly increase our knowledge of the genesis of metalliferous deposits.

The organisation of the institute at its commencement will be as follows:—Signor Immanuel Friedlaender, who has already contributed 100,000 lire and an annual contribution of 10,000 lire, undertakes to collect subscriptions. These will only become payable if up to the first of January, 1912, the total sum promised for the construction and the plant reaches a minimum of 1,500,000 lire, and at the same time an income is guaranteed of not less than 50,000 lire. The legal position of the institute will at the outset be that of a society in which members with a right to vote have contributed at least 10,000 lire or pay 1,000 lire per annum. Members contributing less, so long as it is not under 25 lire per annum, will receive the printed papers and publications of the institute. The idea of an international institute of this description is by no means new. It has been proposed by Prof. Johnston Lavis, Prof. Mercalli, Prof. G. Platania, and five years ago Mr. Cool, a Dutch engineer, published a pamphlet on this matter. The project is already supported by sixty-two prominent names; twenty-five of these are Italians, nineteen are Germans, and three are English.

THROUGH PERSIAN DESERTS TO INDIA.[1]

DR. SVEN HEDIN'S latest book, describing the first section of his famous last journey to Tibet, in which he travelled overland to India, has at the present moment a special political and economic interest, in addition to its varied scientific contributions to our knowledge.

FIG. 1.—Salt Crust in the Kavir. From "Overland to India."

Deliberately avoiding the hackneyed caravan routes through the famous centres of ancient Iran, Dr. Hedin travelled from Teheran eastwards by way of the little explored salt deserts (Kavir), and through Seistan and Baluchistan, to Nuska, near Quetta, where he struck the Indian system of railways. He thus traversed a considerable part of the route over which it has just been proposed, by a group of Russian financiers, to construct a railway to link up the Russian railway lines with those of India, as an alternative, or rather as a rival, to the Bagdad line through Turkish territory to the Persian Gulf. By the proposed line through Persia the journey from London to Bombay is estimated to take less than a week at a cost of 40*l*., as against about 60*l*. for the existing sea route *via* Brindisi, occupying nearly twice that period, whilst the route by Bagdad will not, it is alleged, shorten the existing time very materially. Although Dr. Hedin does not refer to the proposed Persian line, the project for which has been put forward since his book went to the press, the country through which the line is to pass, and the geographical problems in regard to it, are graphically described therein.

Seistan, the most easterly province of Persia, bordering on both Afghanistan and Baluchistan, would be traversed by the line. It has for many years been a territory of great importance in Anglo-Russian politics, owing to its position, standing as it does midway between the Caspian Sea and the Persian Gulf. Although, at present, it is for the most part an arid and inhospitable desert, it is believed that the restoration of its former irrigation works will revive its pristine productiveness, when it was "the granary of mid-Asia"; so that it is regarded as having the possibilities of becoming a second Egypt. Its recovery from the clutches of the desert seems quite feasible. In this connection the process by which the former towns and villages, the traces of which are widespread, have been engulfed by the desert, is considered at some length. The chief factor appears to less climatic change than the cessation of human agency in staying the encroachments of the deserts. The general process of dessication which has been slowly going on in Asia since the Glacial period has proceeded so slowly that it appears to have advanced but little since Alexander's day, subsequent to which the country was much more populous than at present. The early religion of the country has been largely determined and fashioned by what we may call the aggressiveness of the desert. The effect which this has exercised on the minds of the inhabitants finds expression in the old Iranian belief of a beneficent creative power personified in the sun, and one hostile to mankind—Ormuzd and Ahzimrud. As evil associates of the latter are regarded the hot sandstorms, the mirage of the desert, the winter cold, miasmas, and noxious insects and snakes, &c. Hence the practical religious precepts ascribed to Zoroaster are the extermination of those harmful creatures, and especially to stay the ravages of the desert by the planting of trees, constructing water channels, sinking wells, and similar acts. The depopulation of these regions which has permitted the advance of the desert, has obviously been effected mainly by the ravages of devastating wars, intertribal blood-feuds, and the murderous raids of robbers. Under a settled and enlightened Government there seems a fair prospect of these deserts being to a great extent reclaimed, and even the desert of Gobi is not altogether hopeless.

FIG. 2.—Rush Boats on Lake Hamun. From "Overland to India."

At Trebizond, on the Armenian coast of the Baltic, the traveller falls again under the spell of the camel-caravan bells. "I never weary of this same monotonous sound, with its unchanging ryhthm, the ceaseless ding-dong, ding-dong, which I have heard so many times

[1] "Overland to India." By Sven Heden Vol. i., pp. xix+416+map; vol. ii., pp. xiv+357+map. (London: Macmillan and Co., Ltd., 1910.) Price, 2 vols., 30*s*. net.

before, and which awakes a longing for the Sabbath peace of unknown deserts and adventures in untraversed paths."

Not, however, until Teheran was passed does he reach the desert with which the book mainly deals, and on which the traveller camped day after day for several months, excepting at the few oases. In these latter it was occasionally possible to camp under the palms, where "the singing birds which twittered during the day are silent. The jackals start a melancholy serenade, and the soft plaintive song of the desert vibrates through the night." These oases are not entirely pleasurable. They are infested, especially by three venomous creatures: (1) a deadly snake, (2) scorpions, black and white, and (3) a poisonous tarantula spider, which lives out in the desert, but is attracted by the light of the camp fires.

Tebbes, and Dr. Hedin supports Sir Henry Yule's view that the famous Venetian passed here by the direct caravan route between Kuch-benan and Tebbes, in preference to the more modern view of Colonel Skyes and others, that it was by Naibend. It is interesting also to find that Polo's description of this desert "is as correct now as in the year 1272 A.D."

Dr. Hedin's alluring story of his exploration of great scientific interest and importance in itself, is also full of interest for the general reader as well. His numerous sketches and coloured illustrations are admirable and characteristic, but his photographs are exceptionally beautiful. They far surpass in artistic and technical excellence anything to be found in previous books on those regions. The publishers are to be congratulated on their splendid reproduction of these pictures, and on the attractive appearance gener-

Fig. 3.—The Village of Chahrdeh. From "Overland to India."

Wolves levy a heavy tax upon the village flocks. They are individually so well known to the shepherds that each of them has received names, and their haunts are well known. They even attack the camels: "they leap on to the camel's back and crawl down to his neck and tear his throat." Although it was reported that wild camels existed, "no one had ever seen them."

The northern limit of the date palm was found at Tebbes. Beyond this no palm-groves are met with, only a few single specimens in well-protected sites. At Tebbes, where, as throughout southern Persia, the palm supplies the staple food and is otherwise of inestimable service to man, it was calculated that there were 100,000 of the female tree—the male palms are very much fewer in number, and are called "*nehr*," the same word which is used to denote a stallion camel.

Marco Polo is believed to have passed through

ally of the book, which is certain to meet with a wide and hearty welcome.

THE PROBLEM OF INDUSTRIAL TRAINING.

DURING the last few years the feeling has been steadily growing that a large part of the money spent on elementary education is wasted for the want of a proper system of education in continuation schools, whether day or evening, which should prepare children for their future work. Unemployment, the decay of apprenticeship due to the changed conditions of labour, the increased number of occupations for boys and girls which lead to no definite future, and the bookish style of our elementary-school education, have been responsible for this feeling of unrest in the minds of all thinking persons. Some have suggested the reform of the elementary-school curriculum by making it more practical; others the rais-

ing of the school age to sixteen. There is much to be said in favour of both suggestions, and indeed the former is essential; but those who have thought over the problem feel that the raising of the school age will provide no remedy unless what may be called post-elementary or secondary education is directed into channels which will lead up to and adequately prepare children for their future work, whether of a professional, commercial, or industrial character. For professional and commercial occupations ordinary education has done something, but not enough; but for industrial occupations very little has been done except by classes which have been attended by students after a break of two or three years, during which time they have forgotten much that they had learnt at school. The need for some reform in our educational work and for an extension of education in continuation schools has been pointed out in papers read at the British Association meetings, in reports by the British Science Guild and the Consultative Committee of the Board of Education, and at conferences of education authorities.

The resolutions passed and the opinions expressed at the recent conference held at the Guildhall (see NATURE, March 2, p. 31), supported as they were by men and women representing all classes of the community, may be considered as evidence of a strong feeling that the time has come for some definite action to be taken. As an industrial nation we cannot afford to neglect the adequate preparation of our children for their future careers any longer.

Doubtless the commercial training required for professional or clerical occupations presents the least difficulty, because such training is more or less intimately connected with an extension of the curricula of higher grade and secondary schools with a definite objective, and generally there is no opposition to such education. The problems connected with the training of those who will take up occupations of a manual or industrial description are more difficult. As soon as such training is talked about there appears to be a general, though erroneous, fear that such training implies definite trade training, and that the market will be flooded with skilled workers; but an inspection of the work and methods of the schools to which we refer later on will show that this is unfounded. The object of these schools is to prepare those boys and girls who intend to enter various trades, so that they will have an opportunity of becoming skilled all-round workers rather than one-branch hands. The changed conditions of manufacture make some system of preparation in schools and technical institutions an absolute necessity.

In any general scheme, local trade conditions will have to be taken into account by local education authorities in arranging the curricula and in selecting the children suitable for the various types of schools. The number of pupils attending the various types of schools will ultimately be regulated by the laws of supply and demand. The training for industrial or trade occupations, if it is to be successful, must be given in special schools, such as preparatory trade schools, schools of arts and crafts, or technical institutes; and the instruction, whilst not neglecting the general education of the pupils, must include sound preliminary training in the theory and practice of the trades, whether of an artistic, scientific, or mechanical character.

There must be no attempt in such schools to supersede the training of the workroom, workshop, or factory; their aim should be to provide an all-round acquaintance, both theoretical and practical, with the particular trade or group of trades which the pupils will enter, and so to make up in part for the loss of those opportunities of learning formerly provided by the apprenticeship system in various industrial occupations.

A good beginning has already been made in this direction in London by the trade schools for girls, and at the London County Council schools and the Borough and Woolwich Polytechnics; there are similar opportunities for boys at the L.C.C. Paddington and Poplar Schools of Engineering, the Shoreditch Technical Institute for woodwork, the Borough Polytechnic Institute for engineering and metal trades, the Stanley School, the L.C.C. Central School of Arts and Crafts, and at the National Bakery and Confectionary School at the Borough Polytechnic Institute; there are others which might also be mentioned. There are also schools of various kinds in many of the principal towns of the country, such as Leeds, Liverpool, Bradford, and Wigan. In nearly all the schools mentioned the work is a full-time course, but railway companies and large employers of labour in various parts of the country have afforded facilities for their young workmen to attend classes for short periods in the daytime, to enable them to improve themselves both by study and practice in the trades in which they are engaged. Some problems in boy-labour in Government departments are also receiving attention, though much remains to be done.

Without considerable elasticity, no scheme of industrial training in schools and institutes can be thoroughly successful or completely satisfy the industrial and commercial needs of a practical nation such as ours; such training must be post-elementary; that is, must come, not under the regulations governing elementary schools, but under those governing technical schools and institutes, as otherwise there is a danger of limitations in various directions; it may be trammelled by religious questions, by large classes, by rigidity of syllabuses, and will probably suffer from lack of freedom in the choosing of suitable teachers for the work. The type of teachers employed in such schools is indeed one of the most important factors of success, and such teachers must be chosen rather for their special trade and workroom experience than for their academic qualifications. The cooperation of employers and foremen on advisory committees will also form an important feature in the work.

In conclusion, it should be remembered that trade prospers only with a nation which has an adequate supply of technically trained skilled workers. It is generally believed by those who have paid attention to the subject, and it is the opinion of those who can speak with authority, that the trades in which we hold our own are those in which apprenticeship or its equivalent is not yet dead. As the opportunities for apprenticeship in various trades are becoming fewer and fewer, something in the way of a substitute is necessary, and this can be supplied by wise modification and extension of our educational system in the direction of industrial training.

C. T. MILLIS.

DAYLIGHT SAVING?

ON the face of it, the proposed Daylight Saving Bill is distinctly good. For a certain season in the year the clerks in the City of London will get one more hour to spare before the sun goes down. As a result of this they will have more time for the enjoyment of fresh air, more time for outdoor amusements, more time to learn rifle shooting, gain more health, become happier men, and enjoy other benefits. If this is really the case, then the clerks in the west of England, who have for years and years enjoyed 33 per cent. more evening sun than those in the eastern counties, ought to exhibit at least some trace of the benefits which accrue from an extra dose of

daylight. Possibly the inhabitants of Cornwall are really more happy and bright, vigorous and enterprising, than the inhabitants of Kent; but is this really a fact?

Next, where does happiness come in if on a cold spring morning you have to get up one hour earlier? What will the wife and children say to the arrangement? Turning out too soon on frosty mornings, groping about at 4 a.m., to find a box of matches to light the fire, may give rise to domestic irritation, bronchial catarrhs, and other illnesses. Thousands upon thousands of workmen in the north of England, to be at work at 6 a.m., when it is really 5 a.m., will have to disturb their households at the time specified. At the commencement of April a man will get up in the dark, walk to his factory in the dark, and commence work by artificial light. Whatever light and fuel has been saved on the previous evening in the house or workshop will be spent in the dark hours of the early morning. For about six months, or 182 days, which I believe is the period over which the new-fangled time is to extend, men will frequently have to rise before the sun; nature will be asleep, but he must be awake and run counter to Divine intentions. As matters now stand during this period workmen get up on 127 days *after* sunrise. The new Bill will reduce the number of these occasions to 52. He will have been robbed of his morning daylight, and have 75 extra days of morning darkness.

There is not so much daylight saving in the Bill as may popularly be supposed. It gives an hour in the evening, but cuts off an hour in the morning. Will a darkness creating Bill please the British workman?

When to give pleasant afternoons to the few who always go to work in daylight, the workmen in this country, in their trains and trams, and on their "bikes" or on their feet, take to blundering about in the morning dark, it suggests an increase in the number of accidents, more litigation, more illnesses, and more funerals. Doctors and lawyers will have more employment, and insurance companies may raise their rates.

Many medical men are supporting this proposed alteration, and have emphasised the benefits that may accrue from the greater amount of sunlight that people will enjoy if these changes are adopted. Obviously, of course, those requiring more sunlight can, if they will, get up earlier in the morning without any dislocation or changes in standard time. But to compel all workers to get up an hour earlier some months of the year may have effects upon the health quite other than seems to be supposed. Man is largely the creature of habit, and the habits acquired by long usage cannot be broken through suddenly without ill results. When early in April the time is suddenly altered, the result will be that for some days, possibly weeks, workers, clerks, and all others compelled willy-nilly to accommodate themselves to this incompletely considered scheme will find themselves at work, still half asleep, with serious results to their own efficiency, to their own health, and their employers' pockets.

In addition to all this, as I have before said, England, by destroying the time standard of the world, will have gone back on her bargain with other nations, and her steamship and other communications with other countries will have been disturbed.

The defenders of the Bill admit that it has its defects, but they do not point out how these are to be remedied.

To say that different parts of the United States keep different times, and that Cape Colony has found the adoption of the 30th meridian a boon, has nothing whatever to do with the question at issue. These and other countries have adopted a *fixed* time and adjusted their clocks to the Greenwich standard and not to a time that is altered at least twice a year. In these circumstances why references to the United States and Cape Colony have been brought forward I do not understand. The unthinking public might infer that because certain countries have altered their clocks there can be no great harm in altering ours. If this was seriously intended, these arguments are a reflection upon their authors, and indicate that certain reasons for the adoption of the Daylight Saving Bill rest upon curious foundations.

Some years ago, with the assistance of the Foreign, Colonial, and India Offices, I had occasion to inquire into the varieties of time kept by all accessible communities of the world. The only people I remember that have a shifty time are Mahomedans and savages, and it is now suggested that we should take a step downwards and join their ranks.

Astronomers and navigators are, however, to be left in peace. I imagine that those who desire to save daylight recognise that a movable time system might lead to shipwreck and to difficulties in the construction of nautical almanacs, and other astronomical work. If these departments are to be freed from the new arrangements, why should not the same freedom be given to meteorology and all other sciences in which it is necessary to have time observations comparable with those of other countries?

The simplest solution to the whole question would be to commence work one hour earlier in the morning and not confuse ourselves and others by altering the clock. In Japan thousands of schools open in the summer time at 7 a.m., Government offices open at eight and close at two; and what is done in Japan is done in other countries. Surely it is possible for business houses in this country to do something similar.

JOHN MILNE.

THE DESTRUCTION OF LOCUSTS.[1]

A REPORT recently received from the South African Central Locust Bureau bears testimony to the strenuous efforts which have been made during the last four years by the various Government entomologists and others in the systematic collection and tabulation of data regarding the more important phases in connection with the destruction of crops by migratory and other locusts. We congratulate the editor and his colleagues on the most excellent results which they have achieved, and the thanks of the country are also due to them for the valuable assistance which they have rendered to the agriculturists in Cape Colony and elsewhere by the successful methods which they have adopted in checking the ravages of these destructive insects.

In the introduction of the report we are informed that the South African Central Locust Bureau was formed in 1906 through the instrumentality of the Earl of Selborne, then his Majesty's High Commissioner in South Africa. His Excellency saw clearly that several colonies and territories under his supervision would benefit mutually if each were kept informed in regard to locust occurrences and to locust destruction, and measures in the territory of its neighbours, and that it was highly desirable in order that the pest might be intelligently combated, that the origin and movement of invading swarms be elucidated. The 1909 campaign cost the Government a

[1] Fourth Annual Report of the Committee of Control of the South African Central Locust Bureau. Respectfully submitted by the committee to the several Governments supporting the Bureau. Edited by Chas. P. Lounsbury, Government Entomologist, Cape Town, Cape of Good Hope. Pp. 59+15 maps. (Cape Town: Cape Times, Ltd., Government Printers, 1910.)

sum approximating 4000*l.*; even so, it is impossible to estimate its worth to the country, either directly or indirectly; but the editor thinks the saving effected by the campaign may be safely set down as at least a hundredfold. As first of all there is the direct benefit which accrues from the saving of the crops, and, second, the destruction of vast armies of locusts, which will materially lessen if not entirely prevent the recurrence of swarms during the succeeding season.

In comparing the 1909 visitation with that of previous years, it is stated that it was probably the most severe one which has been experienced since 1893, as altogether no fewer than 15,306 swarms were accounted for and tabulated in the monthly returns. These do not, however, take into account the numerous swarms destroyed by the Railway Department or in those districts where there was no locust officer.

The term swarm is of exceedingly vague significance and it is quite impossible to estimate the average size of those which were destroyed. But these may be said to have varied in size from those covering a few square rods to others of such magnitude that they covered hundreds of acres. In the initial stages of the 1909 invasion the insects came down in immense swarms from the Kalahari Desert in March, and subsequently mighty swarms swept the country clean to the coast of the Indian Ocean between Port Elizabeth and East London, the females depositing their eggs more or less all the way from the desert to the sea, where they covered an area of country about 200 miles in width.

The most highly favoured of all the agents used in the destruction of locusts is a mixture of arsenite of soda and treacle. In preparing this the custom is to dissolve 200 lbs. of the arsenite in about 15 gallons of boiling water and then to add water until the bulk is 20 gallons. Half a gallon of this is then poured into an iron drain, specially manufactured for the purpose, and a gallon of the treacle or syrup added; the whole is then thoroughly mixed, the drumhead fixed, and the material is then ready for transport. The dilution of the poison recommended by the department is one part to 66 of water for newly-hatched locusts ("Voetgangers"), and one part to 50 when the insects are about a fortnight old. Mr. C. P. Lounsbury points out, however, that no single means of destruction can be recommended for use in all circumstances, and that spraying with either the arsenical poison or with a soap solution is applicable only where water is available. The soap emulsions make the cheapest spraying solutions for killing the locusts *by contact*, but if the solution is too highly diluted with water the insects may be stupefied for a few hours and finally recover. On the other hand, the arsenical preparation acts as a stomach poison and kills them more or less quickly, according to the strength at which it is used. When poison is used it is lightly sprayed around or over the swarms, or in front of them if they are on the move. This preparation has unfortunately a deadly effect upon the vegetation, and cattle should not be allowed to graze upon the sprayed areas until after a good rain, or after the dead herbage has been fired. Whole areas of crops under cultivation must not be sprayed, and in such circumstances poisoned baits may be used with excellent results, and the most marked feature of the recent work of locust destruction was due to the vastly increased use of such "baits." Various materials are used, but finely-chopped green forage is claimed to be the best. As a substitute bran, mixed with the poison, is also strongly recommended by the officer in charge of the Caradoc district, but it is thought that this may have a deadly effect upon small birds, and is not generally advocated.

One of the most interesting chapters in this report is that which deals with locust-eating birds, the species referred to being the white stork (*Ciconia alba*), though other members of the pelargi are evidently included, and small pratincoles (Limicolæ). It is stated that these birds practically cleared the country of the swarms of locusts that had escaped being poisoned, and that they are the leading factors in the natural control of these pests. This is not the first occasion that the bureau has published information regarding this destruction of locusts by birds; it may be recalled here that information was given in the previous report, in which it was stated that the swarms of locusts which occurred in the country bordering on the Kalahari were practically exterminated by them.

TOTAL ECLIPSE OF THE SUN, APRIL 28, 1911.

Although the eclipse which is due to occur on Friday, April 28, 1911, will only be visible along a narrow track extending from the south-eastern coast of Australia to the islands about Samoa, it has attracted a strong contingent of both official and private observers. In spite of the comparative difficulty of access, it was considered that this, being the last of the series of long-duration eclipses for some years to come, warranted a special attempt being made to secure the important observations, spectroscopic and topographic, which can as yet only be efficiently made during the period of eclipse.

After very careful consideration of all possible situations, most of the parties have proceeded to a small coral island, Vavau, one of the Friendly Group in lat. 18° 39′ S.; long. 173° 59′ W. Three English parties have arranged to observe the eclipse in the vicinity of Neiafu, the chief town of Vavau. The constitution of these, with their instrumental equipment, is as follows:—

(1) *Government Expedition from Solar Physics Observatory.*—Dr. W. J. S. Lockyer, in charge of this party, and accompanied by Mr. F. K. McClean, left London on February 3, 1911, with the necessary gear, and journeyed to Sydney by the Orient s.s. *Otway*. From there the instruments were transhipped to H.M.S. *Encounter*, of the Australian Squadron, and the expedition started for the Friendly Islands on March 25. Their equipment consists of:—

(*a*) *6-inch prismatic camera*, 7 feet 6 inches focal length, with four large objective prisms of 45° angle. With this instrument it is hoped to photograph the spectrum of the sun's atmosphere at second and third contacts, and also to obtain several records of the coronal spectrum during totality. This will be used in connection with a 12-inch siderostat.

(*b*) *Concave Rowland Grating Spectrograph*, of 10 feet radius of curvature, arranged as a slit spectrograph for the first-order spectrum. A special plate holder has been provided, carrying six celluloid isochromatic films, 24 inches long, bent to the curvature of the focal curve. A Cooke photo-visual triple objective of 30 feet focal length, receiving light from a 21-inch siderostat, will form an image of the sun about 3½ inches diameter on the slit plate. An endeavour will be made to photograph the spectrum of the cusps and of the corona during totality.

(*c*) *Cooke Coronograph*, 4 inches aperture and 16 feet focal length.

(*d*) *De La Rue Coronograph*, 4⅜ inches aperture and 8 feet focal length.

(*e*) *Doublet Coronograph*, 5 inches aperture and 30 inches focal length.

(*f*) *Doublet*, 6 inches aperture and 48 inches focal length.

Two small spectrographs will also be used with Thorp replica diffraction gratings placed in front of the camera lenses. To feed these instruments with light two siderostats, of 21 inches and 12 inches aperture respectively, and a coelostat of 16 inches aperture, have been taken by the expedition. On

arrival at Sydney, this party will be joined by several gentlemen who have had experience of eclipse work with Mr. F. K. McClean in Flint Island (1908) and Tasmania (1910). These are Messrs. J. Brooks, W. E. Raymond, and H. Winkelman.

2. *Expedition from the Joint Permanent Eclipse Committee.*—This party will be under the charge of Father A. L. Cortie, S.J., from Stonyhurst Observatory, who will be assisted by Mr. W. McKeon, S.J., and Father E. F. Pigot, S.J. Father Cortie's expedition also travelled by the *Otway* from London, and proceeded to Varau on board the *Encounter*. The equipment is as follows:—

(1) Coronograph of 20 feet focal length.

(2) Coronograph of 4 inches aperture.

(3) Coronograph of 4 inches aperture and 34 inches focus.

(4) 4-prism quartz train spectrograph for recording the ultra-violet spectrum of the chromosphere and corona.

(5) 6-inch Dallmeyer portrait lens arranged as a prismatic camera with a 7-inch objective prism of 42° angle.

3. A private expedition in charge of Mr. J. H. Worthington, who has had a special equipment made for this eclipse. His main instruments will include:—

(*a*) Quartz-rocksalt spectrograph of $2\frac{1}{8}$ inches clear aperture and 4 feet focal length. With this will be used two objective prisms of quartz, 60° angle and $2\frac{1}{2}$ inches high. The length of spectrum given by this combination is 8 inches from D to λ 2600.

(*b*) $3\frac{5}{16}$-inch coronograph with amplifying lens giving an equivalent focal length of 20 feet.

(*c*) $2\frac{3}{8}$-inch coronograph of 4 feet focal length.

(*d*) 3-inch portrait lens coronograph, 24 inches focal length.

Arriving at Vavau early in April, the various parties will have ample time to get their various instruments into the delicate adjustment which is necessary, provided, of course, that they are not seriously hampered by inclement weather. A telegram received from Sydney brings the welcome news that the officers and men of H.M.S. *Encounter* are enthusiastic in their anticipation of helping in the work of the various expeditions, and this augurs well for the success of the eclipse observations if good, clear weather is experienced.

The eclipse occurs at Vavau about 9.15 p.m. G.M.T. on Friday, April 28, totality lasting 217 seconds, with the sun at an altitude of about 43°.

Charles P. Butler.

NOTES.

A committee has been appointed for the purpose of raising in Amsterdam a suitable monument to the memory of the late Prof. van 't Hoff.

Sir J. J. Thomson, F.R.S., has been elected a correspondant of the Paris Academy of Sciences in the section of physics.

The Queensland Government recently appointed Dr. R. Hamlyn-Harris as director of the Queensland Museum, and has issued to him instructions to reorganise and put the museum on a próper footing.

Since the so-called "Daylight-saving" scheme was first put forward, we have pointed out that a change of custom as to the hours of opening of city offices would secure the better use of daylight without legislative action. We are glad, therefore, to see the announcement that in certain departments of the Board of Education the officials arrived at their offices on Monday at 9 a.m. instead of at 10 o'clock, and left at 4 p.m., an hour earlier than usual. The experiment proved such a success last year that the Board of Education authorities have decided to give it a wider trial during the forthcoming summer.

It is proposed, in memory of the late Dr. Louis Olivier, founder of the *Revue générale des Sciences*, to publish a book, of from 250 to 300 pages, containing contributions from eminent men of science and letters who knew M. Olivier. The volume is to appear next August for the anniversary of the death of M. Olivier, and will be accompanied by a booklet containing his portrait, a biographical sketch, and a bibliography of his works. Subscriptions of 20 francs will secure a copy of both publications on ordinary paper, and 50 francs will entitle to copies on Japanese paper. Subscriptions may be sent to M. Louis Brunet, treasurer of the committee, 18 rue Chauveau-Lagarde, Paris.

The Decimal Association has issued a circular with reference to the Colonies and the metric system of weights and measures. The most recent instance of the adoption of the metric system by a British colony is that of Malta, where an Ordinance has been passed making the system compulsory as from January 1 next, or such later date as the Governor may fix. It is understood by the Decimal Association that the question of the introduction of the metric system throughout the Empire will be brought forward by the Australian representatives at the forthcoming Imperial Conference. Accompanying the circular is an interesting summary of official reports on the metric system by Mr. J. H. Twigg, late of the Bengal Civil Service.

The noteworthy flight of Lieuts. Erler and Markenthun from Berlin to Hamburg, and thence to Bremen, has provided a remarkable example of the immediate military value of the aëroplane. The officers started on March 28 soon after eleven o'clock, reaching Hamburg, 142 miles distant, about half-past six. Two halts, each of about two hours' duration, were made, one at Döllen in Mecklenburg, owing to the overheating of the motor, and the second at Ludwigslust. A wireless message was sent from the machine *en route*, which was received at Nauen, near Berlin. The altitude maintained—492 feet to 984 feet—was comparatively small for military purposes, and the flight was aided by a slight following wind. The next day the officers continued the journey to Bremen, covering the distance of 73 miles in a continuous flight of 1h. 15m., aided again by a following wind. The machine used was a biplane built to the designs of the military authorities, with the passenger's seat placed directly behind that of the pilot, but at a higher elevation to enable the observer to obtain an uninterrupted view in all directions. A dual control was fitted, allowing the observer to take charge in the event of the pilot becoming incapacitated from any cause.

A Central News message from Christchurch (N.Z.) on April 1 states that the *Terra Nova* has arrived safely at Port Lyttelton from the Antarctic. During the meeting of the British party with the Amundsen Expedition cordial greetings were exchanged. As already announced, the *Terra Nova*, while following the Great Ice Barrier from the direction of King Edward Land with the view of landing the eastern exploration party somewhere near what was formerly known as Balloon Bight, found the *Fram* in the Bay of Whales. Captain Amundsen's sole object for the present is to reach the South Pole by way of the Beardmore Glacier, but he hopes, after having done so, to carry out the programme of Arctic exploration originally drawn up by him. His equipment includes 116 Greenland dogs and a sufficient number of sledges and skis. The *Terra Nova* on her return to McMurdo Sound left a message in the *Discovery* hut announcing the meeting with Captain Amundsen, and this message Captain Scott will find when he returns from his depôt-laying expedition

in the south. The *Fram* is going to Buenos Aires, and will return to the Barrier in 1912.

THE Prehistoric Society of France will hold its seventh meeting at Nîmes on August 6–12.

Two lectures to engineers, on steel, will be given at the Institution of Mechanical Engineers on Tuesdays, April 11 and 25, by Dr. Walter Rosenhain, of the National Physical Laboratory.

THE Selborne Society has just issued a new prospectus which is well illustrated from photographs by members of the society, and includes pictures by several of the pioneers in nature photography. The prospectus contains a long list of branches and junior branches, with the rules of the society; copies can be obtained by prospective members on application to the honorary secretary at 42 Bloomsbury Square, W.C.

THE death is announced from Rotterdam of Pieter Cornelius Tobias Snellen, the distinguished entomologist, at seventy-seven years of age. A notice in *The Times* of April 5 gives the following particulars of his work:—Snellen devoted his attention almost exclusively to the Lepidoptera, and was one of the founders of the Entomological Society of the Netherlands, in the Transactions of which he published a valuable series of articles both on Dutch and foreign Lepidoptera from 1857 onwards. His work on the Lepidoptera of Holland, published in three volumes in 1867 and 1882, under the title of "Vlinders van Nederland," is the standard work on the subject, and is a model of completeness and accuracy. In addition to his European collection, Snellen brought together a very valuable foreign collection with the assistance of his friend M. C. Piepers, and other Dutch Colonial officials, and on materials thus acquired he based valuable papers on the Lepidoptera of West Africa, Java, Celebes, &c., and he also contributed a long paper on Lepidoptera to Veth's "Midden-Sumatra."

SIR CASPAR PURDON CLARKE, formerly director of the South Kensington Museum, and afterwards director of the Metropolitan Museum of Art in New York, died after a long illness on March 29. Sir Caspar acquired a considerable reputation by his knowledge of Eastern art, of which he was an enthusiastic and earnest student. On behalf of the South Kensington Museum he made several expeditions to the East for the collection of objects of Indian and Persian art, and the very remarkable display of Indian art and Indian architecture, which was one of the most attractive features of the Indian and Colonial Exhibition, 1886, was almost entirely due to the result of the journey which he made the previous year for the collection of suitable examples. After serving at South Kensington in various capacities, he followed Sir Philip Cunliffe-Owen as director of the museum in 1896. Nine years later—in 1905—he was attracted by the liberal offers of the authorities of that museum to the Metropolitan Museum of Art in New York. Illness compelled his abandonment of this post last year, and since his return to England he had been in very failing health.

THE Lötschberg Tunnel through the Bernese Alps was pierced early in the morning of March 31. It has taken four and a half years to bore the tunnel, and it will be another two years before it is open for traffic. The length is rather more than 9¼ miles, and the tunnel ranks third among the great Alpine tunnels. The Simplon is 3¼ miles longer, and the St. Gothard only about a quarter of a mile. One end of the new tunnel, which derives its name from the Lötschen Pass under which it runs, comes out at Kandersteg, in the Bernese Oberland, the other at Goppenstein, 17½ miles from Brigue. The Lötschberg Tunnel differs from the other Alpine tunnels in not being straight, there being three curved lengths of 872 yards, 1222 yards, and 350 yards respectively, amounting in all to about one and one-third miles. This curved course was not part of the original plan, but was necessitated by the accident of July 24, 1908, when the Kander River was tapped and the water rushed into the workings, carrying with it a mass of rock, and killing twenty-five workmen. In consequence of this catastrophe, the total length of the tunnel was increased from 13,735 metres to 14,536 metres, or nearly half a mile. On the approach lines nearly one and a half millions sterling are being spent, while the tunnel itself was to cost 2,000,000*l.* To this sum, however, must be added the extra expenditure, amounting to 80,000*l.*, involved in lengthening the tunnel in the manner described. The chief difficulties encountered have been the hardness of the granite during a great part of the tunnel's course, which has involved heavy expenditure for blasting material, and the high temperature on the south side, which sometimes rose to more than 90° F.

THE Corrosion Research Committee of the Institute of Metals is now actively engaged in preparing for an elaborate series of investigations into the causes of the corrosion of brass condenser tubes. A special condenser is being constructed, which will contain forty-eight tubes, twenty-four of these being made of commercially pure brass, the remaining twenty-four tubes being made from brass containing a single selection from the following:—*lead*, tin, aluminium, manganese, or other materials at the discretion of the committee. Experiments will be made with various water speeds in the ratio of 0 : 1 : 2 : 3 : 4, speed 2 being an average speed used in practice. The circulating water to be used will be obtained from deep water at Formby, off Liverpool, in the first instance, and the plant for the corrosion research will be installed in the University of Liverpool, where the experiments will be under the direct supervision of Mr. G. D. Bengough. It is expected by the committee that the research will occupy many months before any definite conclusions can be reached, and it will undoubtedly be costly. An appeal was recently made by the committee for funds to carry on the research, and in response to it the total amount received was 242*l.* This is sufficient to enable the research to be commenced; but if the work is to be carried on properly the expenses will probably amount to not less than 300*l.* per annum. It is therefore hoped that additional donations to the Corrosion Research Fund will be speedily forthcoming. Donations should be sent to Mr. G. Shaw Scott, secretary of the Institute of Metals, at Caxton House, Westminster, S.W.

THE annual meeting of the Iron and Steel Institute will be held at the Institution of Civil Engineers, Great George Street, Westminster, on Thursday and Friday, May 11 and 12, commencing each day at 10.30 o'clock a.m. On the Thursday morning, the Bessemer gold medal for 1911 will be presented to Prof. H. Le Chatelier, and the Andrew Carnegie gold medal for 1910 will be presented to Mr. Félix Robin (Paris). The awards of the Andrew Carnegie research scholarships for 1911 will be announced, and a selection of papers will be read and discussed. The annual dinner of the institute will be held in the evening in the Connaught Rooms, Great Queen Street, W.C. On Friday, May 12, a further selection of papers will be read and discussed. The autumn meeting of the institute this year will, by the invitation of the Associazione fra gli Indus-

triali Metallurgici Italiani, be held at Turin, Italy, and an influential local reception committee has been formed, under the presidency of Mr. G. E. Falck, president of that association, to carry out the necessary arrangements. The meeting will commence on October 2, and with the subsequent tour organised in connection therewith will occupy about fifteen days from the time of leaving London until the return

In the report of the Royal Zoological Society of Ireland for 1910, the council states that, in spite of the bad weather of last summer, the money taken at the gates has not shown any serious decrease, this being largely due to an increase in the number of sixpenny admissions. On the other hand, the receipts from subscriptions and entrance-fees were distinctly lower. The lions continue to form one of the features of the menagerie, where they are now represented by twenty-one individuals. Lack of funds prevented extensive purchases during the year, but among the additions made in this manner attention may be directed to a young reindeer. The losses by death were serious, and an appeal is made for funds to establish and equip a hospital, by the aid of which it is hoped the mortality may in future be reduced.

In a paper published in the February number of *The Victorian Naturalist*, Mr. J. A. Kershaw shows that the Australian eel (*Auguilla australis*) migrates to the ocean for breeding purposes in the same manner as its European relative, and that in turn the young elvers ascend the rivers until they find suitable dwelling places. As in Europe, these eels, when prevented by dams or on account of living in land-locked lakes or ponds, from reaching the sea by a direct route, will travel during freshets across flooded grass for long distances. Similarly, the elvers in Victoria not uncommonly ascend the streams in large "fares," when, in case of a barrier intervening, they make their way over comparatively smooth surfaces of rocks, as is well shown in the photographs illustrating the paper.

To the March number of *The Zoologist* Prof. McIntosh, of St. Andrews, contributes a sketch of the organisation and habits of the toothed whales. At the commencement the author endeavours to perpetuate the mistake that the "gigantic" mammoth was larger than living elephants, while later on he states that the teeth of the sperm-whale have been asserted to serve as a lure for prey, whereas he should have said the white lining of the mouth. He also asserts that the limbs of zeuglodonts are unknown, and implies that these animals are restricted to America. This being so, it is not surprising to find that he appears to be unfamiliar with the researches of Fraas, Dames, Stromer, and Andrews into the organisation of zeuglodonts, and the discovery of their apparent descent from creodonts. It is remarked that we are still in almost complete ignorance with regard to the slumber of cretaceans—if indeed they sleep at all; and an interesting reference is made to the belief of whalers that rorquals, after filling their lungs with air to the utmost extent, can remain in a quiescent condition beneath the surface of the water for eight or ten hours at a stretch.

The scheme for the administration of the 40,000*l.* granted from the development fund to the Board of Agriculture and Fisheries for the encouragement of light-horse breeding, is now in full working order. It will be remembered that the objects of the grant are five-fold, namely, the award of premiums to stallions, awards for the purchase of half-bred working brood-mares to be stationed in selected districts, free nominations for mares to be served by approved stallions, the purchase of stallions for resale, and the voluntary registration of stallions. The awards to stallions are to take the form of King's premiums and the Board's premiums, and in both cases owners will have to agree to their stallions serving not fewer than fifty mares if required, exclusive of those to which a free nomination has been given. In no case will service-fees be paid for more than ninety mares in any one year. It is estimated that about 200 working brood-mares can be purchased annually, and the free nominations for mares are expected to reach about 1400. By the purchase of stallions it is hoped to keep in the country a number of animals which would otherwise go abroad. One of the difficulties will be that the grant will increase the supply of hunters, cobs, &c., without creating a new market for this kind of stock, the demand for which is decreasing. The answer to this depends in some degree on whether the War Office is prepared to raise the stock of army horses to a war-footing.

In *Meddelelser fra Kommissionen for Havundersögelser*, Serie Fiskeri, Bind III., No. 8, Dr. A. C. Johansen gives a summary account of the recent investigations on plaice and plaice fisheries in Danish waters, treating separately of the fisheries in the North Sea, the Skagerak, and the northern Kattegat. The present memoir gives a very useful and comprehensive summary of the previous reports which have been issued on the same subject. It includes an account both of the market statistics of plaice landed and of the special scientific investigations and experiments which have been carried out. The market conditions in Denmark are exceptional, owing to the fact that the chief demand is for fish which are landed alive. This influences the method of fishing, the plaice being caught in seine nets instead of in trawls. The fish thus caught are for the most part alive when captured, and as there is a size limit (25·6 cm.) below which they are not allowed to be landed, and the fish under this size are returned to the sea, the actual destruction of small fish is insignificant. It appears that since the introduction of the size limit the Danish plaice fisheries in the North Sea have increased, and the report speaks in favour of an international size limit for plaice for all countries carrying on fisheries in the North Sea.

The Legislature of Montana, since January 20 last, has introduced and enacted into a State law a measure that converts the famous "Hell Creek Bad Lands" country into a State game preserve. Primarily it is for the benefit of the prong-horned antelope, mule deer, and mountain sheep still surviving in that wild and picturesque region; but it is reasonably certain, also, that in the future a nucleus of American bison will be added. The region fronts on the Missouri River, and it lies about 100 miles north by west of Miles City. The total area of the preserve is about 100 square miles. About three-fourths of it consists of very deep and rugged bad-lands, made by the waters of Snow Creek, Hell Creek, and other streams. The remaining fourth of the tract contains some high-level grass lands that can support a herd of perhaps a thousand bison. On the eastern side of the preserve lies the fossil region, now known widely as "the Hell Creek formation," discovered in 1902 by Messrs. W. T. Hornaday and L. A. Huffman, out of which have come the great lizard (*Tyrranosaurus rex*) and the giant three-horned dinosaur (*Triceratops brevicornis*). The new preserve contains a small band of mountain sheep. It is intended, eventually, to ask Congress to make Snow Creek a national preserve.

In a recent issue of *The Agricultural News*, the journal of the West Indian Department (vol. ix., No. 223), attention is directed to the possibility of growing Castilloa rubber in Jamaica. It is considered that *Castilloa guatemaltica* is better suited to the local conditions than *C. costaricana*, but it is stated that a drought-resisting Castilloa occurs on the Pacific side of Costa Rica which might prove useful, and is to be tried. The tree should be planted as a separate crop, and not as a shade crop for cacao, if the best results are desired.

The report on the Local Department of Agriculture at Barbados, 1909–10, deals mainly with sugar-cane and cotton experiments. There has been a falling off in the area planted in cotton owing to various discouragements, which, it is stated, would have been greater but for the efforts of the Department. The production and introduction of useful food crops has been continued, with promising results, and a beginning has been made with an export trade to Great Britain. Bananas have been shipped here, and also mangos and Avocado pears, but unfortunately some of the two last crops reached London in bad condition. Sweet potatoes and yams were also sent; from the experience gained it is clear that much has to be learned in regard to time and method of shipment, &c.

Dr. Theiler, of the Transvaal Agricultural Department, showed some time ago that redwater is caused by *Piroplasma bigenimum*, and devised a system of inoculation that has proved very successful in rendering immune the South African cattle. But both in the Transvaal and in Cape Colony considerable trouble has arisen when imported cattle have been inoculated, so many as 33 per cent. of the animals being lost in the experimental trials. The problem is discussed in a recent issue of *The Agricultural Journal of the Cape of Good Hope* (No. 4, vol. xxxvii.) by Mr. R. W. Dixon, who recommends that only young animals less than a year old should be imported if possible, as these resist the ill-effects of inoculation better than older animals. It is further recommended that the importation should be in winter or early spring, at which time tick infestation is in abeyance, and redwater, whether natural or artificially induced, is always milder in cold than in warm weather.

The bush-fire problem in thinly populated countries is discussed by Mr. T. S. Marshall in the Journal of the Department of Agriculture of South Australia (vol. xiv., No. 3). Right through Australia, he states, millions of acres of forest country occur in which many of the trees are ring-barked, others are hollow to the core, numberless dead trees, inflammable as tinder, lie on the ground, while the thick grass and undergrowth become very dry. The fires are started through careless throwing down of burning wax matches—surely the most dangerous of all matches in a forest—by neglect of camp and other fires, by sparks from engines, &c. As a safeguard, breaks are prepared round farm holdings by ploughing a strip one, two, or sometimes more chains wide all round, and keeping it carefully free from growth. In better settled districts brigades are organised and provided with specially constructed carts for sprinkling the ground in front of the fire, and so making a break, or putting out logs and fences that have begun to burn.

The soy bean (*Soja hispida* or *Glycine hispida*) has during the last two years come into prominence as a cattle food in England, and a certain number of experiments have been made to compare it with linseed and with cotton-seed cakes, which have hitherto been the standard purchased foods employed here. A report on two experiments made by Mr. W. Bruce, of the Edinburgh and East of Scotland College of Agriculture, has recently been issued, and the results indicate that soy-bean cake may be inferior to linseed cake for purposes of fattening bullocks. As Mr. Bruce points out, however, the result cannot be considered final. Feeding experiments are liable to many sources of error, and it is not unusual to find that a result obtained in one experiment is not confirmed on repeating the trial elsewhere. Whether the soy-bean cake proved less profitable than the linseed cake is not clear; in one of the two experiments it proved the more expensive food for making flesh, but, in the butcher's opinion, the flesh was worth more.

In *The Agricultural Journal of British East Africa* (vol. iii., part ii.), published by the Agricultural Department, Nairobi, is an article on the rainfall of Nairobi giving diagrams, but, unfortunately, few or no figures, to illustrate various phenomena indicated by the records from June, 1899, to December, 1909. The rainfall is at a maximum in April, when it is 8 inches on the average, though the amount has been so high as 16 and so low as $1\frac{1}{2}$ inches; it then falls, and during the months July, August, and September it averages less than an inch a month, the variation being from drought to 2 inches. It then rises to November, when there is a second maximum at 5 inches, the variation being from less than 2 to nearly 8. According to a native tradition, the rainfall runs in cycles of nine or ten years, each of which cycles terminates with a drought. The records have not gone on long enough to test the validity of this tradition. In another article attention is directed to the loss of power in internal-combustion engines at high altitudes. The writer states that he is working engines at an altitude of some 5000 feet above sea-level, and discusses methods by which the loss, due to diminished atmospheric pressure, may be reduced.

A contribution to the morphology of the Nyctaginaceæ, by Dr. H. Fiedler, published in Engler's *Botanische Jahrbücher* (vol. xliv., part v.), is concerned chiefly with the inflorescence modifications and floral diagram variations, from which the author draws conclusions as to the phylogenetic sequence of the included tribes and genera. The tetracyclic character of the flower with two staminal whorls, characteristic of the Centrospermæ, is confirmed, and evidence for two or more lines of development in the family is adduced.

Two useful compilations by Mr. P. C. Standley relative to the botany of New Mexico are published in vol. xiii., part vi., of Contributions from the United States National Herbarium. The first is an annotated list of type species from New Mexico, together with their localities; to these is added a summary of the itineraries of early collectors, a descriptive list of type localities, and a map of the territory of New Mexico on which the localities are marked. The number of species enumerated is 690, of which one-fifth were collected in the vicinity of Santa Fe, chiefly by A. Fendler in 1847. The second article is a bibliography of New Mexican botany.

A report by Mr. H. N. Thompson, the conservator of forests in southern Nigeria, on his tour through the western districts of Meko and Shaki, provides the subject of a publication by the legislative council of the colony. The forests inland are chiefly open savannah or park-like, in which deciduous-leaved trees predominate; in moist situations along the banks of streams they become denser,

and contain more evergreen species. Extensive areas of the so-called black cotton soil form a special feature that is rare in tropical West Africa. *Pseudocedrela Kotschyi* is the most important tree, both in quantity and quality; *Lophira alata*, the West African oak, and *Pterocarpus erinaceus* are fairly common, and could be increased by judicious fire-protection and cultivation. *Afzelia africana* is more localised, and *Khaya senegalensis* grows mainly above the eighth parallel.

A REPORT on the eruption of Taal volcano (Luzon) of January 30 has been issued by the Rev. M. Saderra Masó, assistant director of the U.S. Weather Bureau in the Philippine Islands. The volcano rises from Volcano Island in Lake Bombon, lies about 39 miles south of Manila, and is 996 feet in height. On the night of January 27–28 the volcano began to emit black smoke from its main crater instead of the usual clouds of white steam. This was accompanied by rumblings and earthquakes. During the next two days the explosions and earthquakes increased in strength and frequency until about 2.20 a.m. on January 30, when a tremendous explosion occurred, which is said to have been heard at a distance of 250 miles from the volcano. A huge black cloud issued from the crater, and there was a heavy fall of boiling mud, which destroyed all the houses and vegetation in Volcano Island and along the western and north-western shores of the lake to a distance of 10 miles from the crater, and caused the loss of more than 1250 lives. Along these shores the mud formed a layer 2 or 3 feet in thickness. The opposite shores escaped with little or no fall of mud, the wind having been from the south-east. The damage was increased by the waves produced in the lake, which reached a height of 10 feet. The rush of air towards the volcano was perceptible for many miles. At Batangos, 17 miles distant, an abrupt fall of 2 mm. in the atmospheric pressure was registered. Volcanic dust was carried so far as Manila. Earthquake shocks, though never of destructive intensity, were extremely frequent, nearly a thousand having been recorded at Manila from January 27 to February 7, when the eruption ended and the ground ceased to tremble.

THE summary of the weather in the several districts of the United Kingdom for the first quarter of the current year, as comprised by the thirteen weeks ended April 1, has just been issued by the Meteorological Office. The mean temperature for the period was nowhere very different from the average, and the record of absolute temperatures was not at all exceptional. The highest temperature in any district during the three months was 63°, which occurred both in the east and south-west of England. The lowest temperature was 11° in the east of Scotland and 13° in the south-west of England. The aggregate rainfall for the period was less than the average in all districts except in the east of England, where the excess for the three months was 0·63 inch. The greatest deficiency was 3·19 inches in the south of Ireland, and in the north of Ireland it was 2·74 inches. The greatest deficiency in any of the English districts was 1·88 inches, in the south-west of England. The largest absolute measurement for the period was 14·42 inches in the north of Scotland, the smallest 3·99 inches in the north-east of England. The number of rainy days was nowhere very different from the normal; the highest number was 58 days in the north of Scotland, the lowest 42 days in the Midland counties. The hours of bright sunshine were in good agreement with the normal; the longest duration was 269 hours in the Channel Islands, the shortest 196 hours in the Midlands. At Greenwich the mean temperature for the three months was in absolute agreement with the average; the rainfall was 0·01 inch less than usual, whilst the bright sunshine was 25 hours deficient. For the six months October to March inclusive, which comprises the whole winter, the mean temperature at Greenwich was 43·0°, which is 0·6° in excess of the average. October and December were decidedly warm months, whilst November was decidedly cold. The lowest shade temperature at Greenwich during the winter is 22°, which occurred both in November and February. Out of 182 days there were 94 days with the temperature above the average, and frost occurred on 37 nights. There were 99 days with rain, yielding a total of 13·31 inches, which is 1·49 inches more than the average; November, December, and March were wet. The total duration of sunshine in the six months was 319 hours, which is 63 hours fewer than the average.

THE meteorological charts of the Atlantic and Pacific Oceans for March and April published by the U.S. Weather Bureau contain useful notices (1) on West India hurricanes, which usually occur between July and October. Particulars are given of some of the more destructive storms, with remarks on the premonitory signs of the approach of tropical hurricanes generally. The tracks of those which occurred in 1900–9 are laid down on charts for separate months. The storms are liable to appear in any part of the region between lat. 7° and 31° N., and east of the ninety-fifth meridian, and to recurve at any point between far to the east of the Bahamas and the west coast of the Gulf of Mexico. (2) Cyclones and anticyclones. The first clue to the rotatory character of storms is attributed to Benjamin Franklin, in 1747. As he was unable to observe an eclipse of the moon at Philadelphia owing to stormy and cloudy weather, while his brother at Boston experienced clear weather, he made inquiries as to the behaviour of the storm in question, and as a result of the investigation he came to important conclusions on the movements of storms in general. Some useful explanations are given by the author of this notice of the conditions at work in weather changes, and of the origin of storms.

THE *Verhandlungen der Deutschen Physikalischen Gesellschaft* for February 28 contains an account of a theoretical and experimental investigation of the best practical method of winding the coil of a needle galvanometer, by Dr. W. Volkmann. Maxwell showed long ago that the wire should increase in diameter as the windings get farther from the centre, and Volkmann finds that the nearest practical approach to this is to make the diameter of the wire used for successive portions of the coil increase in geometrical progression. The loss of efficiency due to this step by step change is proportional to the ratio of the step. The winding should be stopped when the loss due to stopping it is equal to that due to the ratio of the step. By finding experimentally the deflection due to single turns of various diameters, and in different positions, and dividing the deflections by the lengths of the turns, he finds that the best shapes of the parts of the coil are not quite those given by Maxwell, the deviations being greatest for the parts near the needle. With the new winding a coil of only 3·7 cubic centimetres produced the same deflection as a coil of 47 cubic centimetres wound on the old lines. Each coil consisted of four parts, and had a resistance of 5·5 ohms.

The Scientific American for March 18 is devoted to cement and its uses. An interesting article by M. L. Davey gives particulars of methods of saving trees which have partly rotted by means of cement fillings. Once

decay has started in a tree, its progress is rapid. Decay attacks and disintegrates the dormant tissues first, and gradually works outward. Cement in trees fulfils the three-fold purpose of stopping decay, serving as a structural support, and providing a surface over which the bark may heal. Tree surgery may be likened to dentistry; all existing decay must be removed, and means taken to prevent further decay; the cavity must be prepared so that the filling will stay permanently in place, and all foreign substances must be excluded. Chisels and gouges are employed to remove existing decay, which must be followed throughout limbs and trunk so far as it goes. Corrosive sublimate or a similar solution may then be used to destroy any remaining fungi. The walls of the cavity must then be thoroughly waterproofed to protect the wood. Before filling in the cement, the cavity must be well braced, if of considerable size, with steel ribs or truss rods. Skill is required in this matter, so as to allow for the natural swaying of the tree. Water is excluded by cutting a "water-shed" at the edge of the cavity, to which an adhesive waterproofing material is applied. The filling must be under the edge of the bark at every point in order to permit of the bark healing over the filling.

MESSRS. MACMILLAN AND CO., LTD., have published an Index to vols. xi.–xx. (1901–10 inclusive) of *The Economic Journal*, the journal of the Royal Economic Society, which is edited by Prof. F. Y. Edgeworth, assisted by Mr. H. B. Lees Smith, M.P. The index has been prepared by Miss Ethel R. Faraday.

IN our issue of December 26, 1907 (vol. lxxvii., p. 172), attention was directed to Mr. Nasarvanji Jivanji Readymoney's "Science of Nature-History." The author has sent a copy of a reissue of his work—in which he has modified the title and added an introductory page—and also a pamphlet entitled "A Programme of Education," in which he commends the heuristic method of teaching.

MESSRS. BAILLIÈRE, TINDALL AND COX announce that the new edition of Green's "Pathology" will be ready for publication by the end of the month. The work has again been revised by Dr. Bosanquet, much new material added, and rearrangement of subjects made. Its format has also been modified for inclusion in the "University Series of Manuals," which contains such volumes as Stewart's "Physiology" and Dawson Turner's "Medical Electricity."

OUR ASTRONOMICAL COLUMN.

HALLEY'S AND FAYE'S COMETS.—Dr. Max Wolf records, in No. 4486 of the *Astronomische Nachrichten*, recent observations of both Halley's (1909*c*) and Faye's (1910*e*) comets at the Königstuhl Observatory. On March 19 the former was still an easy object for the large reflector, its magnitude being about 14·0; no nucleus was visible, the comet appearing as a round nebulous disc of about ½ minute diameter.

Faye's comet on the same evening was fainter than Halley's, its magnitude as a whole being about 15·0. A sixteenth-magnitude nucleus of about 10″ diameter was situated nearer to the southern edge of the circular nebulous disc; the comet is still an easy object to photograph with the large reflector; an observation on March 23 gave the magnitude as 14·5.

COMET 1910*a*.—An excellent photograph of comet 1910*a*, taken on January 28, 1910, with a Voigtländer "Dynar" objective by Dr. Karl Bohlin at the Stockholm Observatory, is reproduced as a plate in No. 2, vol. xxxiii., of *The Astrophysical Journal*. The principal tail extends to a length of 18°, and is bifurcated at its extremity; in addition, there issues from the slender head a secondary tail 2° long.

Prof. Riccò gives an account of the Catania observations, photographic and spectroscopic, of this comet in No. 2, vol. xi., of the *Memorie di Astrofisica ed Astronomia*. He reproduces several drawings and photographs showing the magnificent main tail and the small secondary one. In regard to the latter, he suggests, with great reserve, that its formation may have been an effect of the proximity of the comet to Venus, the distance separating them on January 27, 1910, being about 133 million kilometres. The Catania drawings for January 22 and 23 show the nucleus to be on the outer, convex edge of the **U**-shaped tail.

A PROPOSED METHOD OF DETERMINING SPECTRAL TYPES QUANTITATIVELY.—On January 24, 1907, we noted in these columns (NATURE, No. 1043, vol. lxxv., p. 304) the results obtained by Dr. Sebastian Albrecht, then of the Lick Observatory, from a study of the varying intensities of certain lines of compound origins found whilst measuring spectrograms for the determination of radial velocities. Briefly, the author found that, in consequence of the variation in intensity of the components from one spectral type to another, there was a progressive variation of the apparent wave-lengths of the compound lines. Further, it was suggested that, by inverting the problem, it might be possible to determine the finer differences in spectral type by careful measurements of the wave-lengths.

In the current number of *The Astrophysical Journal* (vol. xxxiii., No. 2, March, p. 130) Dr. Albrecht, now at the Córdoba Observatory, gives the preliminary results of such an investigation. One of the chief difficulties is to state definitely and numerically the intervals between the several spectral types F, G, K, and M of the Draper classification, but this is overriden by arbitrarily taking them as equal, and making M*a* and M*b* one-tenth of an interval on either side of M. Curves were then constructed with type-intervals as abscissæ and variation of wave-lengths as ordinates, so that accurate measurements of the wave-lengths in the spectrum of the star under discussion would show at once the exact position of that star in the classification; generally speaking, these curves show that the changes in wave-length are regularly progressive from type F to type M.

To illustrate the application of the method, eight stars were chosen, and the selected variable wave-lengths were measured in each, the results being recorded as weighted departures, in tenths of an interval, from the nearest main type. A considerable variation is shown among the individual results from each of the selected lines, although the probable error of the final result from all the lines is, in each case, not great; also, the accordance with the Draper classification is fairly good. Dr. Albrecht considers that the scheme is workable, and that when further developed it will afford a ready method of determining quantitatively the spectral type of the stars observed. He also suggests that in order to avoid special measurement a number of his selected compound lines should be included in all future measurements of spectrograms for the determination of radial velocity; it would appear, however, that for radial-velocity work it is better to use the purest lines possible.

MERIDIAN OBSERVATIONS AT THE ROYAL OBSERVATORY, BELGIUM.—The second part of vol. xii., of the *Annales de L'Observatoire Royal de Belgique* contains the detailed results of more than 2000 observations made with the Repsold meridian circle during 1909–10 (June), by MM. Philippot, Delporte, and Jamar. The principal object was to complete the observations of the *étoiles de repère*, but observations of the sun, the moon, and the planets, and of comparison stars for comets and for use in determining the movements of certain double stars in Burnham's general catalogue, were also made. Since August, 1909, a Repsold registering micrometer has been employed, and during the same year important modifications were made in the meridian room; among other alterations, the foundations of the pillars were encased with insulating material to prevent variations introduced by changes of temperature.

The volume also contains an interesting account of a comparative study of the errors of two chronographs, one by Gautier, the other by Dent.

POPULARISING ASTRONOMY.—From the *Rochdale Times* we see that the Rev. W. G. Pritchard is making an excellent innovation, for the popularisation of astronomy, in connection with the Education Guild of the town. The Guild meets frequently for the discussion of art, science, and literary topics, and the programme for Tuesday night was an open-air talk on the stars. The weather being favourable, the members were to gather in the vicarage field and there discuss the various celestial objects, under the leadership of Mr. Pritchard. We would commend this programme for general adoption among similar associations.

RELATIONS OF PHENOLOGICAL AND CLIMATIC VARIATION.[1]

THE monograph referred to below deals with the flowering date of thirty-nine plants for the years 1896–1909. Unfortunately, only ten, or 25 per cent., were noted for every year, and six were observed in seven to nine only of the fourteen years.

The observations were of herbaceous plants, shrubs, and trees that had grown at least two years in the meteorological enclosure of the Royal Observatory grounds at Uccle, two miles south of Brussels, on level ground, 340 feet above sea-level, all on clay soil. Observations were in each case made on the same individual plant, such as were well exposed being selected. In five chief essentials they were therefore ideal, identity of well-placed specimens, of soil, of location, of elevation, and of the observer, M. Jean Vincent, always on the spot. The series opens with *Corylus avellana*, February 25, and closes with *Aster horizontalis* (1900–7 only), September 15. The months represented are February 1, March 2, April 10, May 14, June 7, July 4, and September 9.

After an introductory survey, in which reference is made to the far greater number of factors now known to influence the flowering date than was once supposed, M. Vanderlinden notes the increasing importance assigned to the completion by each species of its "period of repose," on which, largely, the mean date of flowering depends. The research dealt largely with the influence, in association with this, of meteorological influences, as shown both by observation and experiment.

The test for "flowering," as customary also in this country, was the exposure of the stamens. It is not, however, stated whether for the hazel the pistils were observed instead, these being far less erratic than the staminiferous flowers.

Flowering is much more definite, and therefore better suited for such observations, than other phases, such as leafage, fruiting, and defoliation. The first tables give the flowering date for each year, with the mean for the years observed. It would surely have been well to intercalate dates for the missing years. To do this satisfactorily is indeed rather complicated, and such values are not equal to actual observed dates. But it would be safe to count the error as at most a quarter of that where such precaution is omitted. Thus the mean date given for *Ribes nigrum*, April 10, is that from 1903 on. The corresponding years for *Corylus avellana* give February 19, but that tabulated (on thirteen years of the fourteen) is February 25. For the other years, 1896 and 1898–1902, the average is March 3. The divergence at the later dates, we shall see, would be much less, but the argument would be equally affected. Thus *Ribes rubrum* is given April 10 (1903–9), *R. alpinum* April 14 (1898–1909). But the latter, on the mean of 1903–9, should be April 10·9. These discrepancies are less important for the investigations in hand than had these dealt more specially with relative dates of flowering, but they can hardly be neglected.

In looking at the dates, it is noticeable how much less range there is from the mean in the case of the earlier flowers than in British observations of the few for which there are common records. Thus for the hazel, for Uccle and Purley (Surrey), respectively, the range since 1906 is from February 17 to March 10, and February 1 to March 20; blackthorn, April 11 to May 1, and March 17 to April 27; but for dog rose, May 26 to June 4, and June 1 to 10.

The next subject dealt with is the relation between departures from the mean flowering date and the corresponding variations in the meteorological factors. Comparative curves are given for five such, namely, maximum and minimum temperature, radiation as shown by Bellani's alcohol radiometer, humidity, and rainfall. The last two were found to be relatively negligible, and, in the earlier months, the same is true of the third. Florescence depends, then, mainly on temperature, as the effective food stores are already present. Later on, foliage must precede flowering to supply chlorophyll, which necessitates light. But from June on heat is again the predominating factor, since the interval between foliage and flower is so long. These curves are given year by year. It is by careful examination of these, and confirmation of results, where possible, by experiment, that M. Vanderlinden reaches his conclusions. Naturally, there is always a certain amount of lag, but this is less with the herbaceous plants. The most effective combination is high temperature and radiation, with feeble humidity lasting for several days before the normal flowering date.

The chief experiments consisted in subjecting the plants to warm baths, to moist warm air, to various light conditions, to special warmth treatment over a definite time, followed by ordinary conditions. Some twenty conclusions are drawn, among which, besides those already mentioned, are the following:—

When blooming has been retarded it follows upon less stimulus.

Phenology is practically evidential for temperature and sunshine alone, and then only for approximate values.

Effects may remain latent (and so cumulative) over short periods.

Heredity determines the normal date.

Autumn and early winter have no influence [in Belgium].

Groups flowering concurrently vary concurrently. The evidence given for this is perhaps too limited for the conclusion.

It is certainly so in another case. Anyone who has dealt much with sun-spots would hardly venture on any conclusion from data confined to fourteen years. Hence the statement that no relation shows itself should rather have been that, as the observations have not yet been carried on for fifty or one hundred years, it is too early to investigate the matter. The sun-spot table was hardly the best way to utilise the space. Is not this true also of the fourteen tables of daily temperatures and radiation? One would have been content with a summary to compare with the valuable plates, based upon the figures, if instead we could have had further investigations worked out from the observations. It would have been especially interesting to have had relative results month by month, as, for instance, the relation between annual variation and the cumulative values above some minimum, below which the given plant showed no response to the effective factors of heat and light.

But, in asking for more, it must be understood that this is because of the excellent value of that which is given.

J. EDMUND CLARK.

NON-EUCLIDEAN GEOMETRY.

IT is now well known by all mathematicians that Euclid's theory of parallels is not indispensable for the construction of a self-consistent geometry, but that, on the contrary, there are three coordinate systems, of which Euclid's is one, equally entitled to consideration, and equally general. So far as we can see at present, the strict proof of this statement must be analytical; at any rate, when we suppose that the elements—lines, points, planes, &c.—are, in the space considered, exactly analogous to the corresponding elements in Euclidean space. However, it fortunately happens that we can construct a non-Euclidean geometry in ordinary space by suitably changing the definitions of its elements, and this is, at any rate, of considerable help in convincing a student of the possibility of the non-Euclidean systems. Prof. H. S. Carslaw has recently explained one such method

(Proc. Ed. Math. Soc., 1909–10) which deserves attention as being a very simple image of hyperbolic geometry in Euclidean space.

We start by taking a fixed sphere σ, and define a plane α as a sphere which cuts σ orthogonally, a line as a circle which cuts σ orthogonally, a point as a point-pair inverse with respect to σ. All the ordinary projective axioms are satisfied; the angle between two planes is defined to be the angle, in the ordinary sense, at which the representative spheres intersect. If two planes touch, their point of contact must lie on σ; in this case they are said to be parallel. It is easily proved that through any point (not on σ) two planes can be drawn parallel to a given plane α; triangles exist with each angle zero, and so on. Moreover, it is possible to give a definition of length (as the logarithm of a cross-ratio) which enables us to say that if A, B, C are three collinear points, AB+BC=AC.

If σ shrinks up to a point, the geometry becomes Euclidean, though the elements are not the usual ones. We may, however, abstract from the point S, which is the limiting form of σ, and define a point A in the ordinary sense. Then line and plane elements are represented by circles and spheres through S.

It must be remembered that this theory assumes metrical and other properties of ordinary space, and does not pretend to put hyperbolic geometry on an independent footing. To do this requires a more detailed discussion, and the assumption of a hyperbolic space. In a somewhat analogous way we may consider the question of dimensions in space. We have a real four-dimensional geometry in ordinary space if we take as our primary element a line or a sphere, and so we may construct geometries of any dimension we like. But it is another thing to assume a four-dimensional space where (x, y, z, t) can be taken as, say, rectangular Cartesian coordinates of a point strictly analogous to the corresponding point-element in three-dimensional Euclidean space.

G. B. M.

MICROBIOLOGY IN NEW SOUTH WALES.[1]

WHEN we consider that the report referred to below deals with more than thirty-three thousand examinations, embracing all kinds of subjects, the difficulty of giving any adequate description of the contents will be appreciated. As this report is an introductory one, the plan has been adopted of writing an introduction to each section suitable for non-scientific readers, who may thus be able to follow intelligently the matter discussed; for beyond conducting routine work, the Bureau has set before itself the praiseworthy task of becoming a centre of useful knowledge. But it is further recognised that in the direction of research the Bureau will find its largest sphere of usefulness. This is no doubt true, and it is for the official mind to recognise that the man engaged in routine examinations cannot even succeed at this unless he too is sometimes allowed to engage in research.

To turn to the actual work, we find that tuberculosis ranks first in the numbers of specimens (487) supplied, while typhoid fever ranks second with 214. Perhaps an unnecessarily pessimistic view is taken as to the prospect of being able to control either the "carriers" or the fly in the case of this disease. At present our study of the house-fly is only commencing, and we think it probable that in urban areas it will prove to be very amenable to control. The formula "no dirt, no flies," would express the position we should take up.

It is recorded under the diphtheria examinations that cultures very often do not show diphtheria bacilli in twenty-four, but may do so in forty-eight, hours. But surely one may add the progress of knowledge is slow, for this fact was within the writer's experience twenty years ago when examining cultures in a large hospital. With regard to the protozoa, it is extremely interesting to note that malaria, though prevalent in the northern parts of Australia, occurs only as imported cases in New South Wales, though Anophelines abound there. The unravelling of that somewhat puzzling condition, *paludismus sine malaria*, still demands attention, and here we have another example of it. A large number of new species of bird plasmodia are recorded, though whether these "species" could be distinguished if it were not known from what birds the blood came is, we think, very doubtful. Several new hæmogregarines are also recorded from snakes and tortoises. Besides these scientifically interesting parasites, there are several diseases of unknown causation in cattle of economic importance, *e.g.* endemic hæmaturia in cattle, jaundice in lambs, and black disease in sheep, but piroplasmosis is not recorded. As regards entozoa, those of New South Wales make quite a respectable list, but perhaps by dint of including rarities. Hydatids appear to be the commonest entozoal parasite in Australia, occurring in man, sheep, cattle, and pigs, but rarely in horses.

A very interesting parasite affecting cattle is a filaria-like worm coiled up in subcutaneous tumours, known as "worm-nests." These have excited considerable interest among health officers in London and Liverpool lately, owing to their occurrence in frozen carcases from Australia. They are about the size of a split walnut, and occur, for the most part, over the brisket. It does not appear to be possible that they can be injurious to man. It should be mentioned, however, that it has been stated by one observer that they are associated with tuberculosis, but this is against the weight of evidence. The sanitarian's scruples may, indeed, be allayed by the evidence we have that, although such carcases are used as food in New South Wales, no injurious results have ever been known to arise therefrom.

An examination of telephone mouth-pieces (50) failed to detect tubercle or diphtheria bacilli. The examination of milk preservatives leads to the conclusion that to delay manifest change for even twenty-four hours involves the use of medicinal quantities, the long-continued ingestion of which may be injurious. In the milk question, the means of salvation is, we think, clear—prevention is better than cure. Finally, the rabbit problem must be referred to, and the interesting proposal to destroy rabbits by destruction of females and liberation of males is now being tested.

The director and his colleagues deserve warm commendation for the results of their first year of evidently very laborious work which this report chronicles, and which must soon justify itself, not only scientifically, but also economically.

[1] Report of the Government Bureau of Microbiology for the Year 1909. (Legislative Assembly, New South Wales.)

SCIENCE AND EDUCATION IN THE CIVIL SERVICE ESTIMATES.

THE Estimates for Civil Services for the year ending March 31, 1912, together with a memorandum by the Financial Secretary to the Treasury, have been issued as a Parliamentary Paper. The following particulars with reference to the money under this vote to be devoted to science and higher education are taken from this paper.

Under the sum required for Public Works and Buildings, the Estimate for the Royal Parks and Pleasure Gardens shows an increase of 5725*l.* on the year, in which provision is made for completing the new laboratory in the Edinburgh Royal Botanic Garden at a further cost of 3790*l.* Under Surveys of the United Kingdom (which have shown an annual decrease of cost since 1902–3, when the expenditure amounted to 237,130*l.*), there is a further decrease of 5452*l.* for the year, the estimated net charge amounting to 187,344*l.*

Under the heading Salaries and Expenses of Civil Departments, the Estimate for the Board of Agriculture and Fisheries shows a net increase of 9204*l.*; 43,589*l.* is included in respect of the expenses of a scheme for the Improvement of Light Horse Breeding. The expenditure for this purpose, less a sum of 5000*l.*, will be recouped by a grant from the Development Fund, and the grant of 5100*l.* hitherto paid to the Royal Commission on Horse Breeding ceases after the year 1910–11. 5000*l.* of the increase is, therefore, in effect a transfer from this latter Vote. 2250*l.* is included as grants to local authorities in aid of the provision of local inspectors for the purpose of the Destructive Insects and Pests Acts, 1877 and 1907, and 1050*l.* additional is required for the Collection of Agriculture and Fishery Statistics.

The Estimate for the Government Chemist appears for the first time as a separate Vote. In previous years the salary of the principal chemist was borne on the Treasury

Vote, and the other salaries and expenses of the Government Laboratory were charged to the Customs and Excise Vote.

The Estimate for the Department of Agriculture and Technical Instruction, Ireland, exhibits a net increase of 10,253*l.* Of this amount, 3275*l.* is due to an increased grant-in-aid to the Royal College of Science, and 5500*l.* to an increase in the annual grants to schools and classes of science and art and technical instruction. The sums of 17,000*l.* granted from the Development Fund for the purchase of areas of afforestation, &c., and 10,000*l.* for the improvement of horse breeding, are appropriated in aid of the Vote for this Department to cover the expenses incurred for those purposes.

The total provision for education, science, and art is 19,141,264*l.*, being a net increase of 468,900*l.* on the amount voted in 1910. The Estimate for the Board of Education shows a net increase of 310,840*l.*, of which 229,355*l.* arises under grants in respect of public elementary schools, 13,000*l.* under grants for training of teachers, and 64,500*l.* under grants for technical institutions, schools of art, evening schools, &c.

The Estimate for Universities and Colleges, Great Britain, and Intermediate Education, Wales, exceeds that for 1910–11 by 64,700*l.*, after taking into account a Supplementary Grant of 21,000*l.* in 1910. Of this increase, 10,500*l.* occurs under the subhead for Scottish Universities, and 50,000*l.* under Colleges, Great Britain.

The Estimate for Public Education, Scotland, shows an increase of 82,869*l.* The estimated number of scholars in day schools has risen from 737,576 to 764,397 for the year, and the annual grants for day scholars are increased by 64,647*l.* The provision for grants for continuation classes and secondary schools shows an increase of 16,800*l.*

The increase of 18,176*l.* in the Estimates for Universities and Colleges, Ireland, is due to additional grants for land, buildings, and equipment for the Irish universities.

Among the amounts required for different purposes, the following are interesting:—art and science buildings, Great Britain, 99,900*l.*; surveys of the United Kingdom, 187,344*l.*; Government chemist, 19,088*l.*; Board of Education, 14,375,442*l.*; scientific investigation, 61,603*l.*; universities and colleges, Great Britain, and intermediate education, Wales, 303,800*l.*; public education in Scotland, 2,336,594*l.*; public education in Ireland, 1,653,324*l.*; and universities and colleges, Ireland, 186,256*l.*

A table included in the paper provides interesting information as to the growth of expenditure or otherwise under different headings. Take, for instance, the cases of the Board of Education, and the universities and colleges in Great Britain and intermediate education in Wales, the grants have steadily increased since 1902–3. Under the heading scientific investigations there is no such decided increase to record, as the following table shows:—

	£		£
1902–3	62,932	1906–7	56,868
1903–4	87,300	1907–8	53,823
1904–5	54,484	1908–9	55,349
1905–6	53,343	1909–10	83,338

Grants in Session 1910 for 1910–11, £74,228
Estimates 1911–1912, £61,603.

THE IMPERIAL EDUCATION CONFERENCE.

THE following representatives from the self-governing dominions are expected at the forthcoming Imperial Education Conference, which will be held on April 25–28 inclusive:—*The Dominion of Canada:* The Hon. R. A. Pyne, Minister of Education, Ontario, or Dr. A. H. W. Colquhoun, Deputy Minister of Education, Ontario; Dr. A. H. McKay, Superintendent of Education, Nova Scotia, with whom will be associated the Rev. Dr. MacGill, professor of philosophy, University of Dalhousie; the Hon. George R. Coldwell, Minister of Education, Manitoba; the Hon. Henry E. Young, Minister of Education, British Columbia; the Hon. W. F. A. Turgeon, Attorney-General, Saskatchewan. *The Commonwealth of Australia:* Mr. P. Board, Under Secretary in the Department of Public Instruction and Director of Education, New South Wales; Mr. C. R. P. Andrews, Inspector-General of Schools, Western Australia. *The Union of South Africa:* Dr. Thomas Muir, C.M.G., F.R.S., Superintendent-General, Cape of Good Hope; Dr. W. J. Viljoen, Director of Education, Orange Free State.

The Dominion of New Zealand will be represented by the Hon. Sir William Hall-Jones, K.C.M.G., High Commissioner in London for the Dominion, and the States of South Australia and Tasmania will be represented, respectively, by the Hon. A. A. Kirkpatrick, Agent-General in London for the State of South Australia, and the Hon. John McCall, Agent-General in London for the State of Tasmania.

The following local Governments in India have arranged to be represented as follows:—the Government of Madras by Dr. A. G. Bourne, F.R.S., Director of Public Instruction in the Presidency of Madras; the Government of Bombay by Mr. A. L. Covernton, principal and professor of English literature, Elphinstone College, Bombay; the Government of Bengal by Mr. B. Heaton, principal of the Sibpur Civil Engineering College, Bengal; the Government of the Central Provinces by Mr. S. C. Hill, late Director of Public Instruction in the Central Provinces, and Mr. C. E. W. Jones, principal of the Morris College, Nagpur; the Government of Burma by Mr. W. G. Wedderspoon, Inspector of Normal Schools, Burma.

The representation of the Crown Colonies will be as follows:—Falkland Islands, Mr. T. A. V. Best, Colonial Secretary; Gold Coast Colony, Mr. J. W. Church, Director of Education; Jamaica, Mr. G. H. Deerr, Inspector of Schools; Leeward Islands, Mr. H. E. W. Grant, Colonial Secretary; Malta, the Hon. Prof. Enrico Magro, Director of Public Instruction and Rector of the University of Malta; Straits Settlements, Mr. H. T. Clark, principal of the Malay College, Malacca; Trinidad, Mr. George Goodwille, formerly a Member of the Legislative Council.

The conference will be attended by representatives of the India and Colonial Offices and of all the Home Education Departments—English, Scotch, and Irish. The States of Guernsey, Jersey, and the Isle of Man have been asked to nominate representatives.

The morning sessions of the conference will be confined to official representatives, and devoted to the consideration by them of such matters as the various overseas Governments have suggested for discussion or any delegate may wish to bring before the conference. The arrangements for the afternoon sessions will be announced later. A preliminary meeting of official representatives will be held on Monday, April 24, for the purpose of settling finally the programme for the morning sessions of the conference.

AGRICULTURAL BULLETINS.

THE Agricultural Experiment Station of the University of Wisconsin is one of the most active centres of scientific work in agriculture in the United States. Problems are attacked from two distinct points of view: the economic, in which the object is to show how crops may be produced a little more cheaply than at present, and the scientific, the problem being investigated for the sake of the general principles it may bring out. Two sets of bulletins are therefore issued, the popular bulletin, intended for farmers, dealing mainly with local problems, and always from the local point of view, and the research bulletins. The popular bulletins are fully equal to any others in the United States, and much ahead of anything we publish here for farmers; in the series before us the subjects dealt with include land drainage, curing of seed corn, control of various weeds, draft-horse judging, a discussion of the methods of paying for milk at cheese factories, and so on. The research bulletins are the scientific papers of the staff; as usual in the United States, each paper is published separately, and there is no common journal in which they all appear.

Three of the papers referred to above deal with cheese-making, perhaps the least understood of all agricultural processes. Messrs. Sammis, Suzuki, and Laabs discuss the factors regulating the rate at which whey separates from curd in the cheese vat. High acidity, high temperature, and pressure applied to the curd all facilitate rapid separation, but, on the other hand, variations in the proportions of rennet and the time of action of the rennet have no effect. In another paper Messrs. Suzuki, Hastings, and

Hart deal with the production of volatile fatty acids and esters in the making of cheddar cheese. The acids found were acetic, propionic, butyric, and caproic, but not valerianic acid; none of these seemed to be formed from lactose, although the ethyl alcohol probably was obtained from this compound. Mr. McCollum describes how he succeeded in keeping rats alive for a considerable time on a ration containing inorganic phosphorus compounds and no purine bases; it was necessary for success that the ration should be varied as widely as possible in order to make it palatable. Young rats withstood the unpalatability for a long time, and, indeed, were healthy to the end of the experiment. He concludes that animals can synthesise their complex phosphorus compounds, including nuclein, from inorganic compounds, and, further, that they can synthesise the purine bases from some complex present in the protein molecule. In the last paper of the series Messrs. Hart and Tottingham show the presence of phytin in seeds of maize, oats, and barley. This substance is a complex combination of potassium, magnesium, and calcium with phytic acid, $C_2H_8P_2O_9$, which in turn is broken up on hydrolysis to form inosite and phosphoric acid.

TREE PLANTING IN TOWNS.[1]

THE tree, standing singly, collected in masses forming woods, or grown as a beautiful avenue, is a fascinating object of study once the attention has been arrested upon it. Difficult it is to realise that an object of such size, majesty, and strength as a fine old tree represents has sprung from a tiny seed—a seed which if placed in the palm of the hand may, to the non-expert, prove indistinguishable from the seed of a small herb or grass of the field. Yet in the one case the tiny seed contains within it the germ which will produce a green monument of 100 to 200 feet or more in height, a living monument which will withstand the storms and changes of centuries, and may witness the downfall and uprise of dynasties and nations. Its seasonal garb does not pass through the kaleidoscopic changes of fashion which man in these later days is heir to.

The tree has but the four changes of garment which appear regularly with the changing seasons throughout its life, but this raiment has never failed in its attraction for man. Beautiful as are the tender greens of spring, the deeper, more mature greens of summer, and the brilliant tints of autumn, he who studies trees finds something equally beautiful, even if not more beautiful, in the stern grandeur, with its latent promise of strength, exhibited in winter.

The tree has had a greater influence in the training and civilisation of mankind than is perhaps generally realised, certainly more than is realised by the man of the city and town. Long centuries ago the greater portion of the land of the globe was covered by vast primæval forests in which man lived a primitive existence, and against which he waged an unequal war. But he was dependent upon the forest for the greater part of his means of subsistence, whilst his house, furniture, cooking utensils, such as they were, and implements, offensive, defensive, and cultural, were all fashioned from the materials of the forest.

As man increased in number and became more civilised, he cleared larger and larger areas of the tree growth, and now took to living outside, but still in the neighbourhood of, the forest. Still he depended upon the forest for most of the necessaries of life, from the materials for constructing his house down to a chief portion of his daily food.

It was only with the great increase in number of mankind and with his concentration in certain localities, usually the fertile lowlands from which the forests had been cleared, that these sections of the human race began to depend less and less on the forest as one of the chief staffs of life.

But we see that the instinct of man in the earlier days in the history of the world was to look to the forest as nature's great storehouse from which he could obtain the necessities of his daily life. It is so with the nomadic races of the world at the present day. I wish to make this point, as it explains, I think, the inherent love of trees which lies in the nature of each one of us, though in the city-bred man it may to some extent remain dormant.

It explains another point, on which I propose to briefly dwell, the instinct of man, if left to himself in a bare, treeless region to plant trees or tree growth, or bushes even, to brighten the monotony of his otherwise dreary surroundings. For those of us who have experienced nature in its awesome loneliness in the absence of tree growth of any kind, know full well how appallingly depressing it can become.

In such localities man, if left to himself, will, I say, start planting trees, and will take extraordinary trouble to make them grow. Some years ago I was deputed by the Government of India to visit Quetta, the beautiful capital of Baluchistan—that rugged province situated in the far north-west of India on the frontier of Afghanistan and Persia. Quetta occupies the central Highland of Baluchistan, and is a point of considerable military strategic importance. It is situated at about 5500 feet, and is surrounded by great barren peaks ranging up to 11,700 feet. The railway climbs to it through a dreary rugged waste of rock and sand, with here and there little villages embosomed in trees and surrounded with small areas of crops. It is a wild country, and the history of Quetta fully illustrates my point that man in such a country will plant trees for dear life.

The main station of Quetta was formed after Lord Roberts's march to Kandahar. At the time the first houses were built, save for the fact that the villages around contained some poplars and willows and fruit trees, the site consisted of a barren plain. The planting was first started in 1878 by Mr. Bruce. After the evacuation of Kandahar, the work was taken up mainly by Mr. (now Sir Hugh) Barnes, General Sir Stanley Edwardes, who was in command of the troops, Colonel Gainsford, and Mr. Watson, the forest officer. A tree committee was formed, and large nurseries established. The trees were obtained from Kandahar, a beginning being made in the winter of 1881–2, when some 60,000 cuttings or slips of the chenar or plane tree, poplar and willows, were brought on camels from Kandahar and planted out along the roadsides and in the gardens. The planes were put on the main road, the Lytton Road. They form a magnificent avenue, now thirty years old, which gives a most grateful shade in summer, considerably lowering the temperature. The growth of the trees was wonderfully rapid, irrigation being then, as now, employed to water them; for all the water in the country is brought in channels from the sources of the springs, its value being fully understood by the inhabitants, who show great ingenuity in constructing these water channels. Other roads were lined with poplars or willows, and if a mistake was made it was in planting the trees too close, and in planting the avenues on any one road of one species of tree only; and this mistake had to be paid for later on somewhat dearly, to which allusion may be made. The trees were attacked by a cerambyx beetle pest (*Æolesthes sarta*) the grubs of which fed in the green inner bark—the growing layer—of the trees, and resulted in numbers of the poplars and willows having to be cut out and burnt.

Not only in Quetta, but also in all the cantonments throughout Baluchistan, the planting of trees forms one of the chief recreations of the British community, so great is the distaste of mankind, accustomed and used to tree and plant growth, to exist without it. The whole of the work is carried out by the political and military officers stationed in that portion of the country, few if any of whom had, before reaching the country, any planting knowledge, and many of whom had confessedly previously taken but little interest in the growth of trees. Amongst the most enthusiastic of the planting community at the time of my visit was General Sir Henry Smith-Dorrien, now commanding at Aldershot, but then commanding the Quetta division, and he attacked and wiped out the "borer," as they called the beetle pest, in his cantonments with as much keenness as he planted trees.

I have alluded to the fact that the major portion of the land surface of the globe was formerly clothed with vast primæval forests.

In the opening phases of his connection with the forest

[1] Paper read at the Town Planning Exhibition in the Royal Academy Buildings, Edinburgh, March 23, by E. P. Stebbing, Lecturer in Forestry, University of Edinburgh.

man waged a puny and ineffective war against the relentless growth of the forest, and had as much as he could do to keep a small clearing round his abode, and in many cases this was not attempted. Regions in the tropical world exist at the present day where this unequal and never-ending strife between man and the luxuriant vegetation of the forest still goes on, usually in favour of the forest. With increase of numbers, permanent clearings came into being, but the whole of the materials for house-building, &c., came from the forest. At the present day the aborigines of Central India and the Assam and North Burma Hills, as is the case with aborigines in other parts of the world, construct their habitations of wood, grass, and leaves; their household crockery and glass consists of gourds, with lengths of bamboo for the wineglasses, whilst a considerable portion of their food consists of edible fruits and roots and leaves and shoots of forest trees, and when they can procure it, meat from the wild animals of the same forest.

But man, with increased numbers and civilisation, began a ruthless war against the forest, and is still carrying it on in America, Canada, and elsewhere, with the result which now faces us. In Great Britain, once covered with forests, we have no forests at all and few woods of any size, and are at the present moment entirely dependent on our timber, &c., supplies being brought to us from outside. And the sources of this supply are diminishing, and are also being yearly indented on to a greater extent by other countries.

But long before the awakening as to the importance of forests commenced in Europe—a matter of a century or two only—man, the man in the rapidly growing cities and towns, had realised the importance of the tree and the place the tree held in his existence. His primitive instincts, laid to rest whilst engaged in ruthlessly exterminating his friend, were aroused into an active repentance when he no longer had that friend at his door and could no longer watch it garb itself in its brilliant seasonal changes of raiment, and no longer had its protection for himself and his animals against cold or fierce winds, a hot sun, &c. He then commenced, after the fashion of man, energetically, but more or less spasmodically, to endeavour to repair the effect of his own destructiveness. To his surprise, however, he found it was by no means so easy to replace the trees on spots from which he had ruthlessly cut them. Nature's balance had been unduly interfered with; the rich store of good soil built up through the ages in her own storehouses of the past had been wastefully dissipated, and whereas she herself never asked the trees to grow on bed-rock, man did.

Also, as time went on, the atmosphere, especially in the larger cities and commercial centres, became polluted and vitiated with smoke and acids, and man, having no time or wish to study the methods by which nature reclothes the soil when left to herself after he had passed by, gave up his attempts to maintain trees near or within the areas, rapidly increasing in density of population, in which he worked and lived.

We thus arrive at another stage in the history of man and the tree. The city increased in size; the population doubled, trebled, and quadrupled itself; the single-room tenement, as we were shown by Lord Pentland the other day, made its appearance and came to stay; the streets became narrower, the houses higher, and the tree itself disappeared. If we look at the large densely populated capitals of Europe and the great commercial centres of the present day, we find in both that in the parts occupied by the poor classes and workers the significance of the tree as the close neighbour and companion of man throughout a considerable portion of his existence on the globe has been forgotten or lost to view. But the instinct is there, deep implanted in the heart of each one. Even to the born and bred city child, the descendant of several generations of town-bred men, the craving for a sight of a green field or of a wood comes dimly at times. Probably most of us who are acquainted with great cities have come across instances of such. It was my fortune once to see a little youngster from the slums of London taken into a Kentish hop-field. He came from one of the worst parts of the great city, and in all his little life had only seen a grimy plane tree and a dark, sooty green grass plot. In the train, so soon as the open country had been reached, he remained speechless. Once in the hop-gardens he recovered his voice, and went wild with excitement and delight. It was very easy to see man's instinctive love for wild nature and nature's growth there. Equally apparent is it in most of us born and bred in civilised countries when we come face to face for the first time with a tropical forest. Instincts and thoughts to which we fail to give expression surge up within us as we feel that once again we have come into contact with the original homes of our ancestors; and the feelings, mind you, which are aroused by such a contact, which were aroused in that little London lad in the hop-garden, are the very ones which it is to the interest of mankind to keep alive and stimulate.

Mankind does not seem to improve with his growing habit of congregating in dense masses in cities and towns. He appears, somehow, to lose something of that freshness and breeziness which we associate with the mountain top and find in the dweller on the mountain top. In our more spacious, if less civilised and cultivated, days, we lived in closer touch with nature, and there are those who say that in many ways we were better men for the contact. But the closer life in cities is doing something which, as I think, is even worse for human nature than this. We are losing some of the finer instincts, and certainly our finer senses of sight and hearing, and even of smell. I do not speak from any medical knowledge of the subject, but simply from personal observations made during a number of years' contact with the folk of the jungles and mountainous regions of India. They can give us points and a beating in all of the last three; and yet there is no reason to suppose that our ancestors—the ancient Britons, who dressed in blue paint—were not possessed of these finer senses and were not the equal, in these respects, of the present-day aborigine.

Of course, I do not wish to be understood as saying that the town- and city-bred man can hope to remain the equal of the countryman in his knowledge of nature or in those senses which demand to be constantly used to be kept in high order. But my point is that a good deal more might and should be done to help the dweller in the densely populated portions of the great cities and commercial centres to keep to some extent in touch with nature. He should be able to see and live with trees, and to see daily, not only on holidays or at the expense of a long walk, which he will not take, trees and areas of green grass and flowers. We who live in the open air and habitually enjoy such sights, and those who spend several weeks or months in the year annually in the country, find it difficult to picture the mind of a child who has never seen a field of corn and red poppies rippling under the soft summer wind, or the waving tops of a green forest, or heard the soughing of the breeze in a pine wood; and yet there are probably hundreds and thousands such in these islands.

Now it should be quite possible for the rulers of every large city and town to see that open spaces are provided for the recreation of the inhabitants. Much has and is being done in this respect, and this exhibition is a witness to all it is hoped to do in the future. But I am not concerned here with the provision of the open spaces, but with tree planting and the beautifying, not only of the open spaces, a comparatively easy matter, but of the streets and their neighbourhood. When we talk of trees in streets, the usual idea is, I think, an avenue. Those who have seen the beautiful lime avenue at Trinity College, Oxford, know what a beautiful thing it is. An avenue is a very beautiful thing. But there are many streets far too narrow to take an avenue, and yet it is quite possible that there may be a situation at one or both ends where a tree or a clump of trees can be put; and picture the difference such a clump, changing in colour with the season, will make to the amenity of the street. Or there may be one or more small gardens where small trees or bushes and flowering shrubs might be grown, where bright green grass bands or plots may be put, and which if kept in order can be maintained bright and beautiful. Such clumps and bushes and grass bands and plots are, we know, the natural concomitant of the homes of the more well-to-do portion of the community. But so are they often the accompaniments of the better parts of the city and town. On the Continent, for instance, you do not

want for beauty in the fine boulevards to be found in Paris or Brussels; the Unter den Linden is a thing of beauty in spring in Berlin, whilst the famous Ring of Vienna is as fine a piece of city tree decoration as you could wish to see anywhere.

In these islands we are far behind the Continent so far as the beauty of our streets go. Boulevards as understood on the Continent are entirely absent from most of our big cities. In the exhibition I see on the wall two fine sketches of new proposed roads in Liverpool. These are laid out in the proper spirit, and certainly not one of the least important parts of town planning is the laying out of spacious tree-bordered roads, or even better, because more picturesque, if space is available, with a double line of trees and a walk down the centre of the road, like the Unter den Linden in Berlin. Parks and open spaces we have in our great cities, and very beautiful many of them are. In many cases they are, however, situated at considerable distances from the densely congested poorer parts of the town.

Here in Edinburgh, a city the natural advantages of the setting of which it would be difficult to beat, I can picture George Street as having a very different appearance with a fine green row of trees down each side. I think the addition of a row on the shop side of Princes Street would add beauty to one of the finest streets in Europe, whilst, to mention others, Hanover Street, Frederick Street, and the other streets running off up the slope would look infinitely more picturesque with trees on either side; and once the trees were up they would break the force and chill of the most persistent prevailing wind I have met! But it is not only in the wealthier part of the city that work of this nature should be carried out. Trees should be planted in lines or clumps or as single trees in the poorer and more densely populated quarters of the city. It should not be possible for a child to grow up in any quarter of a city without being in daily contact with trees and plant growth. It should be rendered possible for the town-bred child to know the changes of seasons, not merely by temperature only, but by recognising the early beginnings of life in the year with the first snowdrop, to be followed by the crocus, and shortly after by the budding of the earliest trees. It should be possible for him to know and, if he will, see for himself the trees and other plants flowering and seeding in due season.

It may be said that this will be difficult of realisation in the densely populated poorer quarters of the town. May I tell one more small story which I think points a way?

Some years ago I was stationed in Darjeeling, in the eastern Himalaya. Darjeeling is a town of considerable size, the summer headquarters of the Government of Bengal, and possesses one of the great views of the world, the superb snowy giant Kinchin Junga, to see which and Mount Etna beyond all devout tourists to India make a pilgrimage. The town is situated on a ridge and outlying spurs, the houses embosomed in Cryptomerias, oaks, and other hardwoods. Beautiful as is the place in itself, with its incomparable setting of eternal snows, it came to be recognised that much could be done with the object of beautifying the station. Some of the roads were without trees, the banks and slopes between them overgrown with a tangled jungle growth; the gardens of the houses left much to be desired in many respects; the roads of the bazaar were dirty, and the offshoot paths overgrown with a matted mass of undergrowth, the home and breeding grounds of pestilential flies and microbes. At the instance of the Lieutenant-Governor, the late Sir John Woodburn, K.C.S.I., as fine and broad-minded a type of the British official as could be found anywhere, a motion was set on foot which had for its object identical aims with those, or some of them, the present Town Planning Exhibition is setting before the public—the beautifying of the town so as to render it a better dwelling place for those who had to spend their lives, or a portion of their lives, there. The question, once mooted, was taken up with enthusiasm; and it must be remembered that, as in Quetta, the population concerned mainly consisted of men who would only pass an uncertain number of years in the station, a transfer or final retirement home ending their connection with it. In Darjeeling a strong committee was formed, on which the Government, the municipality, the local bar, merchants, house owners, and private individuals, British and Indian alike, were represented.

The Government recognised, as was pointed out by the Lord Provost at Lord Pentland's speech the other day, that it was not to the municipality (that is, corporation or town council) alone that it should look for the carrying out of the scheme—that the whole responsibility did not rest with the municipality alone. Whilst recognising the necessity of the municipality being the first to move in the matter and promise its support, it was pointed out that every householder in the town had equally a duty to perform in aiding the scheme, and that no scheme could be complete or effectual unless each householder recognised such duty and was prepared to give solid help to further the ends in view. Donations and aid were asked for by the committee from the Government, municipality, and also from the householders, and were forthcoming from each quarter. The committee then proceeded to lay down in broad general lines its recommendations for giving effect to Sir John Woodburn's ideas, and these recommendations dealt with the widening of roads, constructing new roads, building up retaining walls to keep up banks and slopes, planting trees either as avenues or in groups or single trees, the pruning of existing trees which required such work, cutting unsightly undergrowth from banks and slopes and grassing such, cleaning up the gardens of such householders as could not afford to do the work, and in making provision for giving out seed or trees and shrubs where necessary.

The broad principles of the work having been laid down, a strong working committee was appointed, and the whole of the work done in the station in the year I am dealing with was done by that working committee. Householders who were well off were asked to consult personally the working committee as to the details of the improvements to be carried out in their own gardens in so far as they affected the external appearance of the town, and to carry out the recommendations made themselves. They were also asked to aid the working committee by donating seed and plants to be planted in the gardens of the poorer classes. This work was done by the staff of the working committee, and under the personal superintendence of the latter. It was a common sight during that spring, summer, and autumn to see members of the committee supervising work for a couple of hours before breakfast in the morning, men who would be spending the rest of the day in their offices engaged in their ordinary daily pursuits. As a result, the improvement in the appearance of the station was astounding, and fully repaid the time and labour spent on it.

I have quoted this example at some length because it shows that the question of the improvement of a town, and more especially the poorer and more squalid parts of a town, is no Utopian scheme. It should be quite possible to institute similar committees in every large city and town of this country. In the case of the larger ones, such as London, for instance, each local district could have its own local working committee once the broad lines of policy had been laid down.

Here in Edinburgh a working planting subcommittee of the town planning committee might be formed to look after the beautifying of the city so far as such could be advanced by planting work. For the poorer quarters of the town a definite scheme of planting, by which I mean not only the planting of trees and shrubs, but also the formation and upkeep of grass and flowers, should be laid down and worked up too, as funds allowed, it being a *sine qua non* that only such work should be taken in hand as could be looked after and kept up in years to come. To plant a row or avenue of trees and then leave it to take its chance, usually an extremely poor one, of reaching maturity, is to throw away good money. Similarly, to plant areas of grass and leave them to become refuse and rubbish heaps or mud flats is merely to add to the squalor and untidiness of a neighbourhood. For the dwellings of the wealthier inhabitants, advice would be offered when demanded or suggestions made when it was desired to obtain uniformity of treatment in a particular locality or neighbourhood, or when the planting of a group of trees in a garden would afford a pleasing amenity for a neighbouring poorer locality. In the public streets the subcommittee should be given a free hand so far as

tree planting and the formation of grass plots went. I have mentioned above how a street such as George Street, for instance, which has great breadth, could be beautified by an avenue of trees such as black poplars, or sycamores, or elms. In other parts of the city, horticulturists are of opinion that thorns and the service tree might be used, whilst in sheltered situations I should like to try the plane, lime, and even the horse-chestnut. I should like to go into greater detail on what might be attempted in Edinburgh on this head, but for one thing time will not permit of it, and for the other I should require to make a closer survey of the city in this respect than I have yet had opportunity to do.

There is one other point, however, in connection with tree planting in towns which applies alike to Edinburgh and all growing cities and towns. It is concerned, not with tree planting, but with tree felling. It is difficult to speak too strongly in disapprobation of the indiscriminate and pernicious felling of trees which usually takes place when a new block of houses is to be built or a new road laid down. No effort is made to first mark out the foundations or alignment to ascertain whether the trees must come down or can be left to afford a pleasing amenity to the district. Perhaps for the gain of a few shillings or through ignorance or gross stupidity they are ruthlessly hacked down, a few hours destroying the work of a century, and the stumps remain a lasting source of regret to those inhabiting the district, for they can never hope in their time to replace the trees so mercilessly destroyed.

The first rule for a town planning committee to lay down should be that no trees on areas in which building extensions are to take place should be felled or killed without a special permission being previously obtained.

In conclusion, I could wish to point one moral with no uncertain note, and that is the great effect on the amenity of a district and on its inhabitants which tree growth exerts. A barren country is depressing, and has a like effect on mankind, resulting in the coarsening of human nature. Can one be surprised at the low scale of morality and the absence of the finer instincts of human nature generally associated with coal-mining districts when one remembers that alike above and below the surface of the earth the miner finds everything black and lifeless? To merely travel through such a country is depressing. How much more so to live in it? And as it is with the Black Country, as it is called, so is it in the narrow street of the slums, where the blue sky is hidden by the smoke of the great city and plant life of all kinds is absent.

Give the people better homes to live in—it is a first desideratum—but with the houses give them the companions of their ancestors, the trees, the green grass, and the flowers, for there are species of each which, if properly looked after, will grow even in the murk of the great city.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

London.—The Senate at its meeting on March 29 accepted the Galton bequest, and authorised the issue of an appeal for 15,000*l.* to defray the cost of the erection and equipment of a suitable building for the Eugenics Laboratory. Hitherto the laboratory has been housed in the applied mathematics department at University College.

The D.Sc. degree in chemistry was granted to Mr. T. P. Hilditch, an internal student of University College, for a thesis on the relation between chemical constitution and optical activity and other papers; and the degree of D.Sc. in geology was granted to Mr. A. M. Finlayson, an internal student of the Royal College of Science, for a thesis on the geology of ore deposits.

Dr. W. P. Herringham takes the place of Dr. H. A. Caley as a representative of the faculty of medicine on the Senate.

Sheffield.—The council has made the following appointments, among others:—Mr. R. J. Pye-Smith, as emeritus professor of surgery; Mr. Arthur M. Connell, to the lectureship in surgery, which was rendered vacant through Dr. Sinclair White's appointment to the professorship of surgery; and Mr. J. D. Fiddes to the demonstratorship in anatomy.

Prof. Beattie has been appointed representative of the University at the celebration of the 500th anniversary of the foundation of the University of St. Andrews, to be held on September 12–15.

Dr. Alexander Smith has been appointed to the Mitchell chair of chemistry in Columbia University, New York, vacant by the retirement of Dr. C. F. Chandler. He is a Scotsman by birth, and graduated at Edinburgh in 1886. For a short time he was an assistant in chemistry at his *alma mater*. In 1890 he went to America, and has since held professorial posts at Wabash College and the University of Chicago. He is president of the American Chemical Society.

The Joint Matriculation Board of the Universities of Manchester, Liverpool, Leeds, and Sheffield has arranged to examine pupils in the housewifery forms of girls' schools. The examination will be suitable for girls of sixteen years of age and upwards who have studied domestic subjects up to the standard of the school certificate examination. Candidates must offer, in addition to certain other subjects, elementary general science and cookery and two of the following:—housewifery, laundry, needlework and drawing, elementary biology. There will be a practical examination in all domestic subjects.

In *The Economic Journal* for March Mr. W. M. J. Williams deals with the subject of Exchequer grants, and establishes the need of inquisition and action upon the relation of national to local taxation. He urges that a term should be assigned to grants from the Exchequer, that a delimitation should be made of present grants, and that the whole should be settled with a due regard to economy and care by local authorities. Taking the education grants as an example, he considers the problem of a settlement of the relation to be established between national and local finance. We may assume, he says, that the cost of education publicly provided in the United Kingdom is about twenty-seven to thirty millions sterling. Some one half is derived from national sources, and one half of the cost is borne by local authorities, but in addition the central authority bears the cost of central administration and of grants to educational institutions of various kinds. The quota of the cost borne by taxes has grown very considerably since 1870, and local authorities demand that all education charges shall be borne by the Exchequer. In another place he points out that the same public local authority gets sums of money for educational purposes from two departments of State. Altogether, he makes out a strong case for the separation of national and local taxation and finance.

The Legislature of the State of Utah, during its recent session, made an appropriation of 60,000*l.* to the State University for the construction of the main building of the institution. This building is, says *Science*, to house the general library, the art gallery, and the administrative offices. The Legislature also passed a Bill, which has become a law, putting the support of the university and the agricultural college on a permanent financial basis. At present the annual income of the university for general maintenance is about 40,000*l.* New buildings and other constructions are to be provided by special appropriations. The Legislature of Indiana has, we learn from the same source, appropriated nearly 40,000*l.* to Indiana University for the next biennium. This grant includes 30,000*l.* additional maintenance. According to the American Press, a graduate of the Philadelphia College of Pharmacy, whose name has been withheld, has offered to give 200,000*l.* toward the erection of a comprehensive group of three buildings, one of which shall be specially devoted to research work, for the institution. *Science* also records that Mrs. Benjamin Hicks, of Old Westbury, N.Y., has bequeathed 20,000*l.* to Swarthmore College, and that Columbia University has received the sum of 138,600*l.* from the executors of the estate of the late Mr. George Crocker, for the establishment of the Crocker Cancer Research Fund.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, March 30.—Sir Archibald Geikie, K.C.B., president, in the chair.—Captain A. G. **McKendrick**: The chemical dynamics of serum reactions. (1) Amboceptor and complement are opposed in their action on the cell, with the proviso that the former acts as a catalyst to the latter. (2) Complement action is lytic; amboceptoral action is primarily polymerising, or, as the case may be, agglutinative, and secondarily catalytic to complement. (3) The relation of these substances is expressed by the law of mass action, in the form

$$\frac{dz}{dt}=\frac{y}{c}\left(\frac{x}{cz}-z\right)-\left(\frac{y}{c}-z\right)^2.$$

(4) When the substance acted upon is in sufficient quantity this expression describes all serum reactions, viz. hæmolysis, bacteriolysis, opsonin and stimulin reactions, agglutination, precipitation, and toxin action. (5) Toxins are compound, and consist of amboceptor and complement.—G. J. **Burch**: Preliminary note on a method of measuring colour-sensations by intermittent light, with description of an unfinished apparatus for the purpose. Briefly, the new method of measuring colour-sensations is as follows:—A series of flashes of monochromatic light produce by a real induction a condition of colour-blindness in a small area of the field of view, which they surround, but do not invade. This small area is occupied, also in flashes properly timed and proportioned, by the part of the spectrum under examination. The colour corresponding to that of the monochromatic flashes is, as it were, wiped out of it, and the observer sees the boundaries of the underlying colour-sensations so long as the flashes succeed one another at the proper rate.—Dr. E. W. Ainley **Walker**: Variation and adaptation in bacteria, illustrated by observations upon streptococci; with special reference to the value of fermentation tests as applied to these organisms. Numerous attempts have been made to differentiate and to identify varieties of bacteria by means of chemical reactions produced by them in special culture media. One of the most interesting of these attempts was that made by Gordon to prove the existence of definite varieties among streptococci by the use of certain test media. Gordon and those who followed him believe that they can thus subdivide the streptococci into a number of fixed and independent varieties, and classify them into what Andrewes and Horder have spoken of as "provisional species." Their conclusions, however, could only be accepted were it proved beyond question that the reactions on which they rely are stable in character and exhibit constancy. In the present communication evidence is adduced from an extended examination of particular strains of streptococci that the reactions concerned are by no means constant. Under the conditions of ordinary cultivation in agar jelly, and still more under culture in the environment supplied by special media, particular strains of streptococci are shown to exhibit wide variations in their reactions to Gordon's test media. Thus it occurs that strains which are at one time totally different in their test reactions may at another time be found to be identical. Further, it appears that after suitable manipulation particular strains may be made to assume the characters now of one, now of another, of the types supposed to be differentiated by Gordon's tests. The conclusion drawn is that no evidence exists of any fixed or specific differences among streptococci pathogenic for man, but that the differences observed are due to merely temporary and casual variations in the metabolism of these micro-organisms, which thus readily adapt themselves to changed environment. Accordingly it is quite possible that suitably selected tests may be made to afford some valuable indication as to the probable habitat or recent environment of any given strain of streptococci.—W. **Bateson** and R. C. **Punnett**: The interrelations of genetic factors. In the sweet pea it was early found that the distribution of factors among the gametes of plants heterozygous for more than one pair was liable to disturbances of two kinds, known as coupling and repulsion ("spurious allelomorphism"). Coupling affects the factors B, blue, and L, long problem, in such a way that the gametic system is

7 BL : 1 B*l* : 1 *b*L : 7 *bl*.

Other factors may be coupled in systems 15 : 1 : 1 : 15; 63 : 1 : 1 : 63; 127 : 1 : 1 : 127; and presumably other systems of numbers similarly related will be discovered. Repulsion was first seen in the case of B, blue, and E, erect standard, acting in such a way that the gametes are all either B*e* or *b*E. Such repulsion has since been recognised elsewhere both in plants and animals, affecting especially the factor for femalemes. Subsequently it was observed (sweet pea) that two factors, viz. that for dark axil and that for fertile anthers, which had previously been found coupled together, might in another family repel each other. As the result of a long series of experiments, it has been established that if A and B be two factors liable to such disturbances, the F_2 from A*b*×*a*B (or reciprocal) shows repulsion between A and B, but the F_2 from *ab*×AB (or reciprocal) shows coupling between A and B. Two kinds of heterozygote can therefore be recognised, which may be represented as A*b*.*a*B and *ab*.AB. The first, on segregation, makes two types of germ-cell A*b* and *a*B; the second makes four, AB, A*b*, *a*B, and *ab*, with *ab* and AB represented in one of the numbers 7, 15, &c. The polarity of the zygote-cell must therefore be influenced by the way in which the factors come into it, and presumably by the positions which they occupy. The *triple* system, B, L, E, in the sweet pea has only been partially investigated, but it is known that E*bl*×*e*BL gives B and L coupled, with repulsion between B and E, not between B and L. An order of precedence between factors must thus be recognised, which possibly is that of the system of coupling to which they are subject.—Philippe **de Vilmorin** and W. **Bateson**: A case of gametic coupling in Pisum. A variety of culinary pea has for some time been grown at Verrières-le-Buisson having leaflets in place of the ordinary tendrils; this condition is recessive to the normal. The variety has wrinkled seeds. Crossed with a round-seeded normal pea, F_2 showed coupling between the factor for tendrils (T) and the factor for round seeds (R), the coupling being according to the system

63 RT : 1 R*t* : 1 *r*T : 63 *rt*.

Coupling has not previously been observed in Pisum. Owing to the fact that the seed-characters are not quite sharp, the nature of the starch was determined microscopically for each seed before it was sown. This work was carried out on a large scale by Miss C. Pellew at the John Innes Horticultural Institution.—R. P. **Gregory**: Gametic coupling and repulsion in *Primula sinensis*. In *P. sinensis* the short style is dominant to the long style, and the magenta colour of the flowers is dominant to the red colour. A series of experiments was made in which a short-styled race having red flowers was mated with various long-styled plants carrying the magenta-factor. It was found that in the gametogenesis of the hybrid so produced complete *repulsion* took place between the factor for short style and that for magenta colour. Subsequently another series of experiments was made in which short-styled plants carrying the magenta-factor were mated with long-styled reds. It was found that when the cross was made in this way *partial coupling* occurred between the factors for the two dominant characters.

Royal Microscopical Society, March 15.—Mr. H. G Plimmer, F.R.S., president, in the chair.—Dr. Ralph **Vincent**: Some photomicrographs illustrating the morphology of the organisms concerned in the production of acute intestinal toxæmia in infants. These included *B. subtilis*, *B. mesentericus* "No. 7," *B. m. vulgatus*, and *B. proteus vulgaris*. The photographs showed the organisms stained, unstained, and during life. Photographs were also shown of the *Streptococcus lacticus*, the *Bacillus acidi lactici*, and the *B. bulgaricus*.—E. M. **Nelson**: A new piece of apparatus. This consisted of an objective mount fitted with an iris diaphragm, in which the iris was just clear of the back lens, and its movement was controlled by a collar adjustment. The apparatus would no doubt be of great value to workers who employ dark ground for viewing bacteria, &c., as in many instances, owing to defects in the dark-ground illuminator, it was not possible to obtain a dark field when the objective had a wide angle. This fault was remedied by stopping down the aperture of the objective by means of the diaphragm.—E. M. **Nelson**: New objec-

tives and eye-pieces made by R. Winkel, of Göttingen.—J. **Murray**: Report on the rotifers collected by the British Antarctic Expedition of 1909. Forty-six Bdelloids were collected, bringing the Australian list up to fifty-four species. There were seven new species, and eight others occurred as distinct varieties. The new species were *Philodina australis, Callidina armillata, lepida, longistyla, serrulata, mirabilis*, and *Habrotrocha strangulata*. The most aberrant form was *Callidina mirabilis*, which had peculiar fleshy processes on the trunk. The rotifera fauna of the Australian Alps resembled that of Britain. The arid lowlands were very unproductive. Three-fourths of the species, and all the new species, occurred in the Blue Mountains, of moderate elevation. Eight species of non-Bdelloid rotifera were also noted from the water supply and ponds in Sydney.

Zoological Society, March 21.—Dr. S. F. Harmer, F.R.S., vice-president, in the chair.—Mrs. E. W. **Sexton**: The amphipod genus Leptocheirus. In preparing this revision of the genus, the type-specimens of nearly all the species had been examined. The author found that in some cases different stages of growth had been described by different authors as distinct species, in other cases the inadequacy of the original descriptions and figures had led to the introduction of a number of unnecessary synonyms. The specimens of Zaddach's *L. pilosus* and Grubbe's *L. guttatus* had been examined and redescribed, and the number of valid species in the genus was now seven, namely, *L. pilosus, L. pinguis, L. hirsutimanus, L. pectinatus, L. guttatus, L. aberrans*, and *L. bispinosus*.—J. Lewis **Bonhote** and F. W. **Smalley**: Inheritance of colour in pigeons. The paper dealt with the first results of a long series of experiments. Although chiefly Mendelian in character, the authors laid stress on the fact that in several respects their results seemed to point to a further law or laws, which were able to modify the expected Mendelian results, and in regard to which the Mendelian theory offered no satisfactory solution. They showed, for instance, that in chequer and blue matings there was a regular tendency to an over-production of chequers; in the grizzle matings the tendency was to an over-production of blues. Another point apparently inexplicable on the Mendelian hypothesis was the difference in shades of the same colour; by disregarding these and considering them all as gametically identical, the results gave approximately the expected proportions, but, on the other hand, the shades of the different birds undoubtedly affected their progeny, and hence the gametes must also have been affected. The preponderance of a certain sex in a particular colour was also noted, as well as an increase of white in successive generations. No explanation of these phenomena was put forward, as further experiments were still in progress. In dealing with the purely Mendelian aspect of the results, the following points were clearly brought forward:—(1) silver is dilute blue; (2) blue is dominant to silver; (3) chequering and grizzling are both dominant to absence of pattern; (4) grizzling is dominant to chequering; (5) a mealy is a grizzled bird with the white replaced entirely or partially by red; (6) red in a mealy is dominant to white, hence a mealy is dominant to a grizzle; (7) white and grizzling combine to have a common inheritance; (8) red combines with grizzling in the same way as white.—Dr. G. Stewardson **Brady**: Marine ostracoda from Madeira, based on specimens collected by the Rev. Canon Norman, F.R.S., in the spring of 1897. Apart from the species described as new to science, the collection was interesting as extending the known range of several species from the European and North Atlantic areas much farther southward, though not quite into the tropical zone.

Edinburgh.

Royal Society, February 6.—Dr. Burgess, vice-president, in the chair.—W. **Watson**: The isopiestic expansibility of water at high temperatures and pressures. The water contained a small quantity of hydrochloric acid. The apparatus employed was the high-temperature compression cylinder described by Prof. Des Coudres in the Leipzig *Berichten* of July, 1910. The volume change was measured by a method modelled on the electrical methods of Tait, Amagat, and Richards. The dilatometer was made of quartz glass. It was found that, soon after the critical temperature was passed, water behaved for all pressures investigated as an ideal gas, inasmuch as the isopiestics became straight lines. At 400 atmospheres and a range of temperatures from 400° to 500° C., the mean coefficient of expansion of water substance was found to be of the order 0·043. Amagat, working between 100° and 200° C., obtained 0·00099.—H. **Briggs**: An investigation into the effects of errors in surveying. The paper discussed the effects of errors in linear and angular measurements on the accuracy of surveys. A fundamental theorem was that concerning the sum of vector errors, viz. the average error in the position of a point influenced by two or more vector errors is equal to the square root of the sum of the squares of the average magnitudes of the vector errors, and is independent of their relative clinures. Many of the results and methods given are believed by the author to be new. Among these may be mentioned the conclusion that the best theoretical shape of a triangle for triangulation is an isosceles one with an apical angle of 67° 30′. The angle may, however, vary between 50° and 90° without appreciably affecting the well-conditioned character of the triangle, and other reasons lead to the selection of the equilateral triangle as the best for practical purposes.—Dr. W. H. **Young**: Fourier's repeated integral, and on Sommerfeld's form of Fourier's repeated integral.

February 20.—Dr. Horne, F.R.S., vice-president, in the chair.—Miss Dorothy **Court**: The determination of small degrees of enzymatic peptolysis. Abderhalden's method for studying enzymatic peptolysis by allowing the enzyme preparation to act on a solution of pepton prepared from silk and observing the precipitation of tyrosin, is limited in its application by the impossibility in many cases of using clear solutions and by the fact that insoluble products other than tyrosin may be formed as a result of the action. These difficulties are overcome by the filtration of the products of the reaction, and treating the residue on the filter, after drying, with dilute sulphuric acid, and subsequent addition to this filtrate of formol and concentrated sulphuric acid (Mörner's reagent). In the presence of tyrosin a green colour is produced, and the quantity of tyrosin, and thereby the degree of peptolysis, may be estimated by measuring the intensity of this colour by means of the tintometer.—Dr. David **Ellis**: Concerning the new genus of iron bacteria, *Spirophyllum ferrugineum* (Ellis). In this paper, which was a continuation of a former paper, the author met the criticism of Prof. Molisch that Spirophyllum was not generically distinct from Gallionella. In addition to further descriptions, the paper contained some excellent photomicrograms.—Principal A. P. **Laurie**: The temperature coefficient of concentration cells, in which the same salt is dissolved in two different solvents. In addition to the series of experiments described, the paper gave a full discussion of the relationship between the electromotive forces of water and alcohol cells, their thermal properties, and the precipitation of salts by alcohol.

March 6.—Prof. Crum Brown, vice-president, in the chair.—J. P. **Dalton**: The accuracy attainable with a modified form of Atwood's machine. The modification consisted in making one side of the spindle of ebonite, so that as the wheel revolved electrical contact between the two sides of the apparatus became intermittent. By connection with a chronograph, records of distance fallen through and time taken were obtained. The frictional retardation could be determined with great accuracy. The mean of eight different determinations of g gave 980 cm./sec.^{2}, the greatest deviation from the mean being 0·5 per cent. It is probable that a still greater accuracy could be attained with more carefully constructed apparatus than was at the disposal of the author.—J. B. **Ritchie**: The dissipation of energy in torsionally oscillating wires, with the effects produced on the law of torsional oscillations by change of temperature. Peddie's empirical formula $y(x+a)=b$ was applied to the case of wires of brass and other materials, and found to represent the results accurately over a large range of oscillation. The effects of heating were studied fully for brass, aluminium, and copper. In certain cases a sudden change in the value of the constant n was experienced, this change suggesting that a different molecular arrangement was produced at certain definite temperatures. The hardening of the wires

by stretching also produced definite changes in the value of the constants.—J. B. **Ritchie**: An apparatus for inducing fatigue in wires by means of repeated extensional and rotational strains, with the effects produced by such fatigue on the laws of torsional oscillations. The apparatus, designed by Prof. Peddie, is primarily an oscillating pendulum of large moment of inertia electrically maintained, and is provided with an automatic contact breaker. Rotational fatigue was found to have no effect upon the constants in the oscillation equation for brass wire.—Dr. Thomas **Muir**: Boole's unisignant.

MANCHESTER.

Literary and Philosophical Society, March 7.—Mr. Francis Jones, president, in the chair.—Prof. E. **Rutherford**: The scattering of the α and β rays and the structure of the atom. From a consideration of general results on scattering by different materials, the central charge of the atom is found to be very nearly proportional to its atomic weight. The exact value of the central charge has not been determined, but for an atom of gold it corresponds to about 100 unit charges. From a comparison of the theories of large and small scattering, it is concluded that the effects are mainly controlled by the large scattering, especially when the fraction of the number of particles scattered through considerable angles is small. The results obtained by Crowther are for the most part explained by this theory of large scattering, although no doubt they are to a certain extent influenced by small scattering. It is concluded that for different materials the fraction of particles scattered through a large angle is proportional to NA^2, where N is the number of atoms per unit volume and A the atomic weight of the material. The main results of large scattering are independent of whether the central charge is positive or negative. It has not yet been found possible to settle this question of sign with certainty. This theory has been found useful in explaining a number of results connected with the scattering and absorption of α and β particles by matter. The main deductions from the theory are at present under examination, in the case of the α rays, by Dr. Geiger, using the scintillation method.—Dr. H. **Geiger**: The large scattering of the α particles. Geiger and Marsden have shown that a small fraction of the α particles incident on a thin film of matter are so scattered that they emerge again on the side of incidence. In the present paper the fraction of the α particles scattered through various large angles by a thin gold foil has been experimentally determined by the scintillation method. Radium emanation enclosed in a fine glass tube was used as a source. The microscope to which the zinc sulphide screen was attached moved round the arc of a circle; the distance between the scattering material and the screen was constant and equal to about 2 cm. The source of radiation, the scattering foil, and the screen were enclosed in a metal vessel, which was exhausted to a low pressure. The number of α particles scattered through large angles up to 150° was first measured, and, as the emanation decayed, the number of small angles was successively determined. The number of scattered particles per unit area varied, when corrected for decay, nearly 300 times over the range of angles examined. The actual numbers of particles observed varied very approximately as $\operatorname{cosec}^4 \phi/2$, where ϕ is the angle of deflection. This is the relation theoretically deduced by Prof. Rutherford in the foregoing paper.—R. F. **Gwyther**: Can the parts of a heavy body be supported by their elastic reactions only?

PARIS.

Academy of Sciences, March 27.—M. Armand Gautier in the chair.—The president announced the death of S. Arloing, correspondant in the section of rural economy.—A. **Lacroix**: The peridotites of New Caledonia.—A. **Müntz** and E. **Laine**: The nitrogen losses during the purification of sewage by bacterial beds. It has been shown in previous papers that the nitrogen losses average 50 to 60 per cent. The present note deals with the forms in which the nitrogen escapes. If organic matter is absent and the nitrogen is present as ammonia salt, no loss occurs, but the losses increase with the proportion of organic matter present. It has been found that the nitrates are reduced to gaseous nitrogen.—Pierre **Termier**: The mylonites of the island of Elba. The existence of these rocks in Elba points to a general and intense crushing action, and leads to a new interpretation of the structure of the island.—J. **Carpentier**: A tension meter, for measuring the pull exerted by metallic wires in aëroplanes.—C. **Guichard**: The C networks, such that the lines of a series should be plane curves.—F. **Gonnessiat**: D'Arrest's comet. A discussion as to the cause of the increase of intensity of luminosity over that calculated according to the law of inverse squares.—Henri **Lebesgue**: The invariance of the number of dimensions of a space and on Jordan's theorem relating to closed varieties.—Georges **Léry**: Green's function for an algebraic contour.—Maurice **Fréchet**: The notion of a differential.—André **Broca**: The constitution of axes of rotation sufficiently stable to permit the measurement of the geodesic angles by the method of repetition.—Félix **Michaud**: The causes which may produce the variation, at constant temperature, of the vapour pressure of a liquid. The curvature of the meniscus is not the direct cause of the capillary variation of vapour pressure.—E. **Henriot**: The radiations of the alkaline metals. Potassium salts emit a very penetrating ionising radiation, that from rubidium salts being less penetrating but more intense. Cæsium salts give no appreciable ionisation, an unexpected result. The causes of the marked differences between the radiation of the metals and their salts is discussed.—A. **Leduc**: Application of principles to a case of magnetostriction.—M. **de Broglie** and L. **Brizard**: The mobility of the ions produced in air by the hydration of sulphate of quinine. The ionisation of air produced by this salt belongs to the type of rapid recombination, and the measurement of the mobility of these ions presents special difficulties. The present note describes how these difficulties have been overcome.—Maurice **Joly**: A static means of tripling the frequency of alternating currents.—Maurice **Coste**: The metallography of the gold-tellurium system. Details are given of the methods adopted for purifying the tellurium and preparing the alloys. Only one compound appears to be formed, $AuTe_2$, and there is direct evidence against the formation of the compound Au_2Te of Margottet.—P. **Pascal**: Magneto-chemical researches on the atomic structure of the halogens.—Ath. I. **Sofianopoulos**: Two new compounds of stannous chloride with ammonia.—E. **Dumesnil**: The preparation of an arsenic amalgam. Arsenic amalgam is obtained by reducing a solution of arsenious acid and mercury bichloride in hydrochloric acid by sodium hypophosphite. The composition of the amalgam corresponded to As_2Hg_3.—Alexandre **Hébert**: The pyrogenous decomposition of the metallic xanthates. Eleven metallic xanthates have been examined, and a table is given showing the nature and amount of the gaseous and liquid products. The canthates of nickel and mercury give the ester $C_2H_5O.CS.SC_2H_5$ in good yields.—Léo **Vignon**: The action of water vapour upon carbon in presence of lime. The principal gaseous products are hydrogen and methane, together with carbon monoxide and dioxide, oxygen, and nitrogen.—Paul **Lebeau**: Some definite bismuthides. Remarks on a recent paper by A. G. Vournasos on a method of preparing sodium bismuthide.—L. **Hackspill** and R. **Bossuet**: The temperature at which water is attacked by the alkaline metals. The globule of the metal, previously distilled in a vacuum, and with a perfectly bright surface, is cooled to a given temperature, and water vapour allowed to condense on the metal; the alteration of pressure caused by the evolution of hydrogen indicates the reaction. Cæsium is attacked at −116° C., rubidium at −108°, potassium at −105°, and sodium at −98°. It would appear that the reaction is between metal and vapour, and not metal and solid ice.—Marcel **Guichard**: The gases given off by the walls of glass, porcelain, and silica tubes. Jena glass gave about 0·03 c.c. of gas per 100 sq. cm. of surface; with porcelain the results were variable, but the quantity was about three times that of the Jena glass. Fused silica gave as much as 2 c.c. of gas per 100 sq. cm. surface.—M. **Lespieau**: A method of preparing certain true acetylenic alcohols. The method indicated in a previous communication, based on the action of methylmagnesium bromide upon monobromacrolein, has been generalised, and additional acetylenic alcohols are described.—M. **Godchot** and F. **Taboury**: The catalytic addition of hydrogen to cyclopentanone. The products of the reaction

are cyclopentane, cyclopentanol, and a compound $C_{10}H_{16}O$, isomeric with camphor, formed by the interaction of two molecules of the cyclopentanone and one molecule of hydrogen.—L. **Duparc** and M. **Wunder**: The serpentines of Krebet-Salatim (North Ural).—MM. **Tschirch** and **Ravasini**: The wild fig in its relations to certain types of cultivated fig.—François **Kövessi**: New researches on the supposed utilisation of nitrogen from the air by certain special organs of plants. The development of the specialised organs studied by Jamieson, Zemplen, and Roth is not interfered with by the complete absence of gaseous nitrogen, and hence cannot be regarded as causing the assimilation of this gas.—M. **Desroche**: The phototropism of the zoospores of *Chlamydomonas Steinii*.—A. **Desgrez** and F. **Calus**: The ptomaines of tinned fish and crustacea. All the samples examined contained ptomaines in proportions between 0·2 to 0·6 gram per kilogram. The bases thus isolated are relatively slightly toxic.—Jean **Gautrelet** and Louis **Thomas**: The influence of the ablation of the suprarenals on the nervous system.—Jules **Glover**: Classification of the voice.—MM. **Bordas** and **Touplain**: Considerations on the estimation of phosphate in the ash of milk. No phosphorus is lost in reducing milk to an ash.—Gabriel **Bertrand** and M. **Javillier**: The combined influence of zinc and manganese on the development of *Aspergillus niger*.—L. **Massol**: The action of ultra-violet light upon starch. Under the influence of rays from a quartz mercury lamp, starch loses its property of bluing with iodine, and the solution acquires reducing properties.—R. **Bierry**: The digestive ferments of the hexotrioses and of stachyose.—E. **Brumpt**: The decimation of the stags of the forest of Chantilly by worms.—E. L. **Trouessart**: The Indian wolf, *Canis pallipes*, and its relations to the domestic dog.—E. **Sollaud**: *Desmocaris trispinosus*, a type of a new genus.—MM. **Grenet** and **Salimbeni**: The resistance opposed to the passage of micro-organisms by filtering candles with collodion layer.—E. **Bataillon**: The two factors of traumatic parthenogenesis in amphibians.—Armand **Dehorne**: The non-copulation of the exchanged nucleus and of the stationary nucleus, and the disappearance of the latter in the conjugation of *Paramecium caudatum*.—Stanislas **Meunier**: The otogenic efficacity of earthquakes.—A. **Briquet**: The morphology of the Gallo-Belgic littoral.—Ph. **Négris**: The discovery of Eocene breccia in Greece and their importance.—Jean **Brunhes**: The confusion produced by the use of the morphological pseudo-term "cala."—Ch. **Moureu** and Ad. **Lepape**: The constancy of the ratio of krypton to argon in natural gaseous mixtures. This ratio was measured in twenty gases of natural origin, and was found to be nearly constant.

DIARY OF SOCIETIES.

THURSDAY, APRIL 6.

ROYAL SOCIETY, at 4.30.—*Bakerian Lecture*: A Chemically-active Modification of Nitrogen produced by the Electric Discharge: Hon. R. J. Strutt, F.R.S.—Papers: The Association of Lead with Uranium in Rock-minerals, and its Application to the Measurement of Geological Time: A. Holmes.—The Path of an Electron in Combined Radial Magnetic and Electric Fields: Dr. H. S. Allen.—On the Dynamical Nature of the Molecular Systems which emit Spectra of the Banded Type: Prof. E. T. Whittaker, F.R.S.

ROYAL INSTITUTION, at 3.—Surface Combustion and its Industrial Applications: Prof. W. A. Bone, F.R.S.

LINNEAN SOCIETY, at 8.—On the Brown Seaweeds of the Salt Marsh: Miss S. M. Baker.—On the Genus Salicornia: Dr. C. E. Moss (History, Synonymy, and Phylogeny), E. J. Salisbury (Characters of the Species), and Dr. Ethel de Fraine (Anatomy).

RÖNTGEN SOCIETY (King's College), at 8.15.—Secondary Rays: Prof. Barkla.—An Improvement in High Tension Discharge Apparatus: Prof. Wilson.

INSTITUTION OF NAVAL ARCHITECTS, at 11.30 a.m.—Diesel Engines for Sea-going Vessels: J. T. Milton.—The Influence of Longitudinal Distribution of Weight on the Bending Moments of Ships among Waves: F. H. Alexander.—Considerations affecting Local Strength Calculations of Ships: J. Montgomerie.—At 7.30: The Acceleration in Front of a Propeller: Dr. R. E. Froude, F.R.S.—An Investigation into the Stresses in a Screw Propeller Blade: Engineer-Lieutenant A. Turner.

INSTITUTION OF ELECTRICAL ENGINEERS, at 8.—Wireless Telegraphy Working in Relation to Interferences and Perturbations: J. E. Taylor.

FRIDAY, APRIL 7.

ROYAL INSTITUTION, at 9.—A New Method of Chemical Analysis: Sir J. J. Thomson, F.R.S.

MALACOLOGICAL SOCIETY, at 8.—A List of Marine Shells occurring at Christmas Island, Indian Ocean, with Description of New Species: E. A. Smith.—Description of *Oxytes Beddomei*, n. sp., from Burma: Lt.-Col. H. H. Godwin-Austen, F.R.S.—Note on the Habits of *Eurychlamys platychlamys*: Major A. J. Peile, R.A.

INSTITUTION OF NAVAL ARCHITECTS, at 11.30 a.m.—Results of Trials of the Anti-rolling Tanks at Sea: Dr. H. Frahm.—Steering-gear Experiments on the Turbine Yacht *Albion*: H. S. Hele-Shaw, F.R.S., and F. L. Martineau.—Description of a Stability and Trim Calculator: S. B. Ralston.—General Propositions and Diagrams relating to the Balancing of the Four-cylinder Marine Engine: C. E. Inglis.—At 7.30: The Determination, by Photo-elastic Methods, of the Distribution of Stress in Ships' Plating: Prof. E. G. Coker.—Some Notes on a New Design of Merchant Vessel: M. Ballard.

INSTITUTION OF CIVIL ENGINEERS, at 8.—Retaining Walls: E. F. Farrant.

GEOLOGISTS' ASSOCIATION, at 8.—(1) The Scenery of Gloucestershire; (2) On the Sections of Forest Marble and Great Oolite on the Midland and South-Western Junction Railway between Cirencester and Chedworth, Gloucestershire: L. Richardson.

SATURDAY, APRIL 8.

ROYAL INSTITUTION, at 3.—Radiant Energy and Matter: Sir J. J. Thomson, F.R.S.

MONDAY, APRIL 10.

ROYAL GEOGRAPHICAL SOCIETY, at 8.30.—On the Plans of the Australian Antarctic Expedition, 1911–1912: Dr. Douglas Mawson.

TUESDAY, APRIL 11.

INSTITUTION OF CIVIL ENGINEERS, at 8.—*Further discussion*: The Improvement of Highways to meet Modern Conditions of Traffic: J. W. Smith.—Recent Development in Road-traffic, Road-construction and Maintenance: H. P. Maybury.

WEDNESDAY, APRIL 12.

ROYAL ASTRONOMICAL SOCIETY, at 5.

CONTENTS.

THURSDAY, APRIL 13, 1911.

PROBLEMS OF SEXUAL AND ASEXUAL REPRODUCTION.

Lehrbuch der vergleichenden Entwicklungsgeschichte der wirbellosen Thiere. By Prof. E. Korschelt and Prof. K. Heider. Erste und Zweite Auflage, Allgemeiner Theil, Vierte Lieferung. Erste Hälfte. Pp. 167–470. Price 7.50 marks. Zweite Hälfte. Pp. 471–896. Price 11 marks. (Jena: Gustav Fischer, 1910.)

EMBRYOLOGISTS who are already acquainted with the "Lehrbuch der vergleichenden Entwicklungsgeschichte der wirbellosen Thiere"—and what embryologist is not?—will welcome with delight the appearance of these further instalments of the "Allgemeiner Theil." No pains have been spared in the preparation of these two volumes, and authors and publishers alike are to be congratulated on their achievement.

In the first the student is introduced to the earliest important phase in the differentiation of the sexually produced individual organism—the formation of those "elementary organs" long since known as the layers of the germ. An admirably lucid account is given of the various types of "gastrulation," or endoderm formation, and this is followed by a description of the development of the mesoderm. The latter part of the treatise is devoted to the study of the peculiarities of these processes in certain special groups, Sponges, Arthropods, and Chordates (Cephalochorda and Urochorda).

It seems almost ungenerous to criticise where the general level of attainment is so high, but we confess that we should have liked to see the Vertebrates included in the last chapter—the method of closure of the blastopore, its relation to the chorda and neural plate are so similar in all these forms—and it is certainly a pity that no attempt has been made to deal with the derivation of the Amniote from the conditions found in Anamnia—a problem long the despair of embryologists, but now happily solved with the help of the Gymnophiona. And we might venture to remark perhaps that Fig. 154A, on p. 248, is incorrect in not exhibiting the bilateral structure of the egg, due to the formation of the gray-crescent on fertilisation. These, however, are matters that hardly mar the excellence of the book.

The second volume makes even more fascinating reading. One by one we are shown, in the groups of the animal kingdom, the details of the mechanism by which a new individual is produced from a bud, processes simple enough in some cases, but often presenting the most amazing complexities, which reach their acme in the Ascidians, while at the same time they defy—notably in Polyzoa and Ascidians again—the rules observed in sexual reproduction, and challenge the observer to frame any formula which will embrace the infinite variety of their behaviour.

But description is but the beginning of embryology, as of any other science, and the baffling problems presented by the germinal layers will assuredly only yield, if at all, to the experimental method. The results which that method has obtained must indeed form the starting point of any discussion, the basis of any theory of the part played by these "elementary organs" in development.

The old germ-layer hypotheses, which all more or less trace their lineage back to Haeckel's famous "Gastræa-Theorie," assume that the stage at which these sets of cells are segregated is of phylogenetic significance, reminiscent of some bygone ancestry, and that there is a general agreement not only in the way in which the layers originate, but also in the structures to which they eventually give rise, as is, of course, necessary for the hypothesis.

And though the authors of this treatise very properly define the germ-layers as the rudiments of definite body tissues in normal development, they are yet concerned to attempt some defence of a position which is no longer tenable.

Even in sexual reproduction there are too many refractory facts: thus, a two-layered condition is not necessarily a separation of endoderm from ectoderm (Placental Mammals, Cestodes, Phylactolæmata), the gut of Cœlenterates is formed in various ways, and so in Vertebrates the roof and floor of the archenteron play varying parts in the formation of that organ, while in those groups in which the egg segments according to the "spiral" type, it is by no means necessary that a cell or cell-group which has a definite place and time of origin in the cleavage system should invariably give rise to the same larval or embryonic part, though, it is true, this usually occurs. The cell 4*d*, for instance, is not always mesoblastic, and even when it does give rise to the mesoblastic bands the destiny of those structures may be variable. In Annelids, the cœlom is developed in them, in certain Mollusca they break up into connective tissue while the (cœlomic) pericardium has another (ectodermal) source.

These are only a few instances. When, however, we turn to the conduct of the layers in budding matters are infinitely worse. In Polyzoa the whole of the alimentary canal is of ectodermal origin; in Turbellarians nervous system and pharynx are mesodermal; in Annelids the pharynx is endodermal, all these organs being in sexual reproduction developed from the ectoderm. In Cephalodiscus the gut is ectodermal instead of being derived from the parental endoderm. In the Tunicata these anomalies attain the perfection of irregularity. The nervous system may be ectodermal (Botryllidæ), endodermal (other Ascidians), or mesodermal (*Pyrosoma*, Salps, Doliolidæ). The atrium may be ectodermal (Botryllidæ), endodermal (other Ascidians), or mesodermal (*Pyrosoma*, Salps), while the pharynx may be ectodermal (Botryllidæ, Doliolidæ), or endodermal (other Ascidians).

These facts, as the authors admit, nay insist, are indisputable, and absolutely irreconcilable with the requirements of the ordinary germ-layer theory.

An effort is indeed made to save the situation by minimising the discrepancies that occur in the course of sexual reproduction, and removing the facts of

budding to another category. The writers, in fact, suggest that the phenomena are not coordinate, and that there would have been no difficulty had not "prospective significance" been confounded with "prospective potentiality." That is, it is the peculiarity of a bud to contain sets of cells which have greater capacities than the embryonic layer from which they were derived in the other manner of development. And yet, when it becomes necessary, to find some general expression for the different modes of endoderm formation in Cœlenterates, to deduce them all from some common origin, the "prospective significance" is enlarged until it is big enough to include as much "potentiality" as may be required!

The truth is that the anomalies are of the same order in both kinds of reproduction. In both the germ-layers have greater potentialities than they normally display, and no theory of them can ever be satisfactory that does not offer a general explanation of their origin and differentiation, in the development of the ovum, in budding, and in regeneration.

To the phenomena of the last two kinds the test of experiment has, as yet, scarcely been applied, but we do fortunately know what the internal factors are on which the differentiation of these first-formed embryonic organs in the ovum depends. For experiment has shown us that there are in the cytoplasm of the unsegmented egg-cell certain substances—at least certain regions—the removal of which entails the absence in later development of some particular embryonic or larval structure. The position of these substances in the ovum need not be that in which the corresponding organ eventually appears (the apical sense organ of *Dentalium* depends on something present in the polar lobe of the egg), and the manner in which this heterogeneous cytoplasm is cut up into cells during cleavage is largely irrelevant, the cleavage pattern being alterable, and, further, determined by other, distinct, causes. Hence, though normally these organ-forming stuffs pass into definite cells, though in related forms the cleavage pattern is alike, but not identical, though in related forms the arrangement of the stuffs and the differentiation of the organs is alike but not identical, nevertheless variations in the cleavage unaccompanied by corresponding variations in the cytoplasmic structure (or the converse), necessarily lead to the production, in related forms, of the same organ from a cell which has in cleavage a distinct origin. The illustration applies primarily to "spiral" cleavages—the nephridia of Leeches comes from 4*d*, of Annelids from 2*d*, the pericardium of some Mollusca from ectoderm, of other Mollusca and of Annelids from mesoderm (4*d*), and so on—but, *mutatis mutandis*, may be easily extended to other cases.

In truth, the substances out of which genuinely homologous, that is, phylogenetically homogeneous organs are developed, must be themselves homologous. They exist in the egg antecedent to segmentation and gastrulation, and cannot be created by those processes, in which therefore we look in vain for any absolute criterion of homology.

What experiment has done for the developing ovum it will, we hope, before long accomplish also for the bud and the regenerating organism. Then, but not until then, shall we know what the internal factors of differentiation are in these cases also, and shall be able perhaps to show that the primary—eventually all—the phenomena of their "increase of structure" are determined by the same kind of material (ultimately physical and chemical constitution), as that on which they are dependent in sexual reproduction.

WEBSTER'S NEW INTERNATIONAL DICTIONARY.

Webster's New International Dictionary of the English Language. Based on the International Dictionary of 1890 and 1900. Now completely revised in all Departments, including also a Gazetteer and other Appendices. Edited by Dr. W. T. Harris and F. S. Allen. Pp. lxxx+2620. (London: G. Bell and Sons, Ltd.; Springfield, Mass, U.S.A.: G. and C. Merriam Company, 1911.) Price *2l. 13s. 6d.* net.

THE origin of "Webster" dates from a notable period in the history of works of reference, the second half of the eighteenth century. Noah Webster, a teacher in the United States, entered upon his earliest work of compilation about the same time that "a society of gentlemen in Scotland" were producing the first edition of the *Encyclopaedia Britannica* in Edinburgh. His spelling book appeared in 1783; it doubtless contained the germ of his larger idea, though this was not developed for many years—the first edition of his dictionary only appeared in 1828. Apart from re-issues and supplements (and also, to judge from a warning in the prospectus, pirated editions), there have been two great revisions of the original work before the present one, namely, those of 1864 and 1890. Both in the method of presenting facts and in mechanical construction the "new" revision introduces changes so great as to justify the use of the epithet in every sense, and some of these changes are of much importance and interest to all who have been led by frequent use to formulate views on the right arrangement of works of reference.

In the first place, "Webster" is an "encyclopædic" dictionary, and in the present edition that quality has been not only sustained but brought into greater prominence. At one period in the history of the making of works of reference, strong criticism was directed against the encyclopædic type of dictionary, and on obvious grounds. It was held to be the function of a dictionary exclusively to state and account for, historically and philologically, the origin and meaning of each word, to attempt no disquisition as to its connotation, and to avoid any articulated arrangement of historical, scientific, or other information dependent upon any word as a "heading." This latter function was left to the encyclopædia exclusively. Proper names and place-names were ruled out on the same grounds. On the other hand, the encyclopædia did not trench upon the philological functions of the dictionary, nor even, to any

great extent, upon its explanatory function. But his doctrine gave a secondary place to the consideration of practical utility to the "ordinary reader," and (to put the case on no higher ground) ignored the dependence of the work of reference upon the ordinary reader for any commercial success. After all, commercial success connotes wide utility. The encyclopædic method in a dictionary offers the reader something more than the bare solution of his ignorance of the meaning of any word; it may offer him connotation (in limited doses) as well as denotation; it may assist him, as "Webster" does, by appropriate pictorial illustration.

The encyclopædic method ought not, on one hand, to be used to the exclusion of the philological and other "purer" functions of the dictionary. Nor does the new "Webster" appear to transgress this provision. On the other hand, it is obvious that encyclopædic information must be strictly limited by considerations of space, and this makes exceedingly difficult the judgment of how far it should be included at all. Therefore the following instances (by no means isolated) taken to suggest that the present editors have carried the encyclopædic principle too far, are offered with due diffidence. Under the heading "Geography," after the general definition, there follow the main divisions of the science—mathematical, physical, &c., with their scope explained—very properly. Under "Geology" the same arrangement is given, and the various branches—cosmical, stratigraphical, and the like—are referred to. Then follows:—

"Geology is of comparatively recent development. Its basis as a true science may be said to have been laid by James Hutton (1726–97). It was advanced by the investigations of William Smith (1769–1839), and notably by the teachings of Sir Charles Lyell (1797–1875)."

And so the notice ends. It is submitted that this information, thought it might have formed the introduction for a brief treatise, is, by itself, practically valueless. Take, again, the homely instance (picked at hazard) of the notice on "Football," which defines the difference between the various codes of the game so far as to indicate the allowance or exclusion of the use of the hands, but gives no hint of difference in methods of scoring, or in the numbers of players constituting sides. This is surely a partial, and therefore wrong, application of the encyclopædic method.

Every allowance ought to be made to the editors of a general work of reference in their endeavours to save space. It is therefore possible to condone the method, theoretically indefensible, by which each page of the new dictionary is made up in two parts. In the upper and larger, all words of more common use (within a very wide range) are given in triple-column arrangement. In the lower, obsolete and local words, equivalents, alternatives, uncommon compounds, and the like, calling for only slight reference, are given in an arrangement of six columns of painfully small type. An excellent feature is the printing of an easy reference to the signs used to indicate pronunciation, at the foot of every page. In planning these signs, such eccentricities as inverted letters have been happily avoided.

The illustrations do not reach the mechanical standard of other departments of the book. The coloured plates at the beginning, showing arms and flags of various nations, are indifferent, both in drawing and (at any rate in the impression before us) in colour-register, while many of the cuts illustrating the text are of somewhat archaic cast. A large selection of the latter are repeated at the end of the volume under a series of general headings, such as agriculture, anatomy, antiquities, and the like. The utility of this is not obvious; the classification reveals a certain degree of partiality, and the cuts, crowded together *en masse*, look frankly ugly.

The encyclopædic method has been held to justify, and with reason, the inclusion of a gazetteer and a biographical dictionary among the appendices. The names in these appear to have been methodically chosen. As this feature has been retained from the former issue, we do not entirely follow the editorial judgment in including scriptural, classic, and other proper names, characters of fiction, and the like, in the body of the dictionary. Such arrangement may tend to confusion on the part of the user of the book. On the other hand, he will be the more ready to excuse any difficulty in this direction in consideration of the ease with which any desired letter or section of the work may be found, for the makers have retained the familiar and excellent system of indicating sections by marked indentations in the margin of the pages, so that the closed volume may be opened at any desired place. Finally, it may be said that though the additions to the matter of the work as a whole are so numerous as to have more than doubled the number of entries in the previous edition, and to have added several hundred pages, the bulk of the volume is not seriously increased. Such criticisms as have been offered above are recognised to be mostly upon debatable ground, and it is freely admitted that the new edition does nothing to mar, and much to add to, the established reputation of "Webster."

O. J. R. H.

GLAUCOMA AND ITS CAUSE.

Glaucoma. By Dr. Thomas Henderson. Pp. xv+222. (London: Edward Arnold, 1910.) Price 10*s.* 6*d.* net.

GLAUCOMA is that condition of the eyeball in which the intraocular tension, normally greater than the superincumbent atmospheric pressure by about 20–25 mm. Hg., is pathologically still further increased so as to produce various deleterious results. It has hitherto been generally held that variations in the intraocular pressure are produced by changes in the amount of the fluid contents of the globe; that alterations in the quantity of blood may be considered negligible in this respect; and that such variations as occur affect the lymph of the eye. The lymph is thought to be secreted by the ciliary processes, and to be excreted through the so-called "filtration" angle of the anterior chamber into the venous plexus which goes by the name of the canal of Schlemm. On

this theory the intraocular tension will vary with the relationship of secretion to excretion of lymph. It is clearly a postulate of the theory that some alteration in the volume of the globe occurs under differing internal pressures, though the necessary amount may be so slight as almost to escape the ordinary crude methods of experimental analysis.

Dr. Henderson propounds a theory which is merely the application of the Monro-Kellie doctrine of intracranial pressure to the eye. This theory of intracranial pressure has been proved substantially true by the researches of Mr. Leonard Hill, and Dr. Henderson, postulating the constancy of volume of the eyeball under all pressures, physiological and pathological, embarks upon a bold attempt to make all the arguments fit in the case of the eye. He holds that in the normal eye the total volume is constant, the circulatory system is elastic, and that diffusion takes place between the contained fluids and the return (venous) circulation. Hence the intraocular pressure is equal to the venous pressure of the elastic system. In glaucoma the total volume is fixed, and there is an absence of diffusion between the contained fluids and the return circulation. Hence the fluid and incompressible contents act as a rigid volume, converting the elastic circulatory system into a rigid one. The outflow pressure of a rigid system is always higher than that of a similar elastic system of tubes. Therefore the intraocular pressure is raised, as the lowest circulatory pressure is that of a rigid, not an elastic system. The starting point of the process in glaucoma is held to be sclerosis of the cribriform or pectinate ligament, whereby the diffusion of the aqueous into Schlemm's canal is hindered. The explanation of the success of iridectomy as a cure for the disease is founded upon the fact that wounds of the healthy iris stroma do not cicatrise in the ordinary manner of connective tissues. The aqueous is thus brought into more intimate contact with the iris veins, and is enabled to drain away.

It will be realised from this brief account that the theory is revolutionary in its relation to certain hitherto accepted facts. In some such instances the author has audaciously thrown over the facts. The most striking example of this procedure concerns the anatomy of the ciliary circulation. No one has previously questioned Leber's brilliant researches on the circulation of the eye. Dr. Henderson, from an exhaustive examination of serial sections, asserts that the circulus arteriosus iridis major is not an artery but a vein. Adopting the teleological argument that there is no rhyme or reason for such an abundant arterial supply to so insignificant a structure as the iris, it is an easy step to transform arteries into veins for the benefit of the theory. We do not consider that the examination of serial sections can possibly prove the point conclusively, unless the blood-vessels have been previously injected, as was done in Leber's researches. It may be hoped that Dr. Henderson or others will adopt this more conclusive test.

Dr. Henderson's fundamental postulate, that of the constancy of volume of the eyeball under physiological and pathological pressures, cannot be accepted without reserve. The walls of the eye, though rigid, cannot be regarded as rigid in the same sense as the walls of the cranium. There is experimental evidence to the contrary, notably that afforded by the researches of Koster Gzn. Further, there is positive evidence of vasomotor changes in the intraocular blood-vessels, a fact which militates against the theory.

Moreover, if the intraocular pressure is purely a question of transmitted hydrostatic pressure in the sense of the term as used by Dr. Henderson, why does the pressure fall slowly and gradually when the eyeball is excised? This and other questions will have to be answered satisfactorily before the theory can be adopted. There is no doubt, however, that the author has elaborated an important element of the problem. His work should be read by all physiologists and ophthalmologists, and cannot but prove to be stimulating to thought, and, it may be hoped, to further experimental research.

EXPERIMENTAL THERAPEUTICS.

Einführung in die experimentelle Therapie. By Prof. M. Jacoby. Pp. vii+180. (Berlin: J. Springer, 1910.) Price 5 marks.

UNTIL the middle of last century therapeutics was a purely clinical study, the physician treating his patients on purely empirical grounds and without any clearly conceived idea of how his measures affected the course of the disease. About fifty years ago the experimental study of the action of drugs was taken up by a number of investigators, and the school of experimental pharmacology succeeded to the ancient study of materia medica. The benefits accruing to medicine from this school are recognised by all who have followed the course of therapeutics in the last half-century; but its members in some degree have stood aloof from the great movement which, beginning with the discovery of pathogenic organisms, has progressed to the discovery of their antidotes in the antitoxins, and to the treatment of disease by these last. The workers on therapeutics who have approached the subject from the bacteriological laboratory have accordingly assumed a new and distinct title for it—experimental therapeutics—and show a tendency to broaden its borders to include such work as that which has culminated in Ehrlich's discovery of the new antisyphilitic specific. Yet the methods followed by Ehrlich are exactly similar in essentials to those of Schmiedeberg or von Mering in their researches on hypnotics; and the fact that the former was seeking a remedy to act on the treponema in the tissues, and the others for a remedy for the over-excited nerve cell, does not seem to justify their subjects being classed under different headings.

The book before us seeks to give a bird's-eye view of the position of the subjects in therapeutics which have recently been investigated experimentally. Beginning with some examples of pharmacological antagonism, the author leads us through the development of the therapeutics of the internal secretions (*Substitutionstherapie*) to the experimental investigations on antiparisiticides; under this he groups the treatment with vaccines, antitoxins, and Ehrlich's

new arsenic compounds. Short chapters are devoted to the therapeutics of tumours, inflammation, blood-diseases, gout, fever, and disturbances of the circulation and digestion so far as these have been determined by experimental methods. It is, of course, impossible to treat this extensive programme exhaustively in 174 pages, and the author seems rather to have aimed at giving a general idea of what is being done to advance therapeutics experimentally with the object of arousing the interest of the students and younger practitioners of medicine in the subject. The book seems well fitted to attain this object, for it is written in an easy style, and deals with some of the most interesting topics in medicine at the present time. On the other hand, the chapters are very unequally written. In some instances pages are devoted to detailed description of surgical methods (pp. 34–36) or of individual experiments, which seem out of place in an introductory handbook, while other subjects are treated too briefly for anyone to follow except the expert; and there is very little attempt made to differentiate the fundamental experiment from the less important or less generally accepted result.

The author tends too often to leave the solid ground for speculations which are often based on experiments which, to say the least, have not yet received general assent. In a book primarily designed for German medical students, perhaps it is right to direct their attention chiefly to authors of their own nationality whose works they can read, but we cannot help thinking that some of the chapters would have been improved by wider reading. For example, the chapter on vaccines might have been rendered more intelligible and also more up-to-date.

The book is not free from serious errors; for example, where (p. 11) it is stated that Hunt found alcohol protects mice against the nitriles; and the antidotal effect of sodium sulphate in barium poisoning is surely due to the barium being precipitated, and not to the restoration of the sodium, as the author supposes (p. 13).

PROJECTIVE GEOMETRY.

Projective Geometry. By Prof. O. Veblen and Prof. J. W. Young. Vol. i. Pp. x+342. (Boston and London: Ginn and Co., 1910.) Price 15s. net.

In the first page of their introduction the authors say:

"The starting-point of any strictly logical treatment of geometry must be a set of undefined elements and relations, and a set of unproved propositions involving them; and from these all other propositions (theorems) are to be derived by the methods of formal logic."

Here, in a nutshell, is the modern mathematician's creed; and it is significant that it should thus appear in a treatise on projective geometry, which at first sight would seem to be one of the most intuitive of the branches of mathematics.

In accordance with the above dictum, the authors give a brief discussion of the axioms of geometry so far as they are required for the purposes of this volume, rightly, we think, deferring the more complete theory of order and continuity to a later stage. Enough, however, is done to make the reader aware of the numerous tacit, and often complex, assumptions made in the ordinary treatment of the subject. For instance, we have an explicit statement of the fundamental postulate:

"If A, B, C are points not all in a line, and D, E are distinct points such that (B, C, D), (C, E, A) are respectively collinear, then there is a point F such that (A, B, F) and (D, E, F) are respectively collinear."

With the help of this and a few other assumptions, a plane is defined in such a way that it can be *proved* that if A, B are any two points in a plane, every point of the line AB is in the plane. No one can fail to see that this is an improvement on the Euclidean definition of a plane, which is a question-begging assumption, based no doubt on the practical tests applied by masons and carpenters.

After this the reader is introduced to the fundamental operations of projection and section, and to the principle of duality. The latter is very properly stated, at the outset, with reference to three-dimensional space: that is, point and plane are correlative terms, not point and line. It is easy enough to deduce the special laws of duality for two-dimensional fields; and the more general form of statement at once brings home to the student the fact that, as a rule, the propositions of projective geometry arrange themselves in sets of four, only one of which need be formally proved. For instance, Pascal's theorem for a conic in a plane leads at once to Brianchon's theorem, and two corresponding theorems for a quadric cone.

Even yet it may be asserted that von Staudt is the great master of projective geometry, much as Gauss is the incomparable arithmetician. It is one of the great merits of this work that the influence of von Staudt's work is so apparent in it. For instance, involution is treated at a comparatively early stage; and this is important for several reasons. In the first place, it simplifies the proofs of many fundamental properties of conics; in the second, it shows the existence of a polar system, in a plane or in space, apart from the assumption of a quadric curve or surface defining it. Ultimately, of course, the best definition of a conic or quadric surface is that it is the locus of self-corresponding points in a polar system. This, with Staudt's theory of imaginary (or complex) elements, permits of the inclusion of "imaginary" conics and quadrics as actually existing things. It is to be hoped that the second volume will contain a sufficient account of Staudt's beautiful theory, which, as a rule, seems to be very imperfectly apprehended. As he unfolds it in the supplements to his "Geometrie der Lage," it is purely geometrical, though no doubt he was led to it by analysis—at least, this seems the most probable assumption.

Among the interesting points of the present volume there is a brief account of Staudt's theory of "throws" (*Würfe*), and his constructions for addition and multiplication. In the latter there is a slight modification, arising from a change in the order of deduction. What is here shown is that if we take any three points

on a line and provisionally label them $P(o)$, $P(1)$, (∞), and if $P(x)$, $P(y)$ are provisional labels of any other two points, then there are projective constructions defining $P(x+y)$ and $P(xy)$, such that the laws for adding and multiplying labels obey the ordinary laws of algebra, *e.g.* $P(x+y)=P(y+x)$, including the limiting cases when x or y, or both, have one of the special values 0, 1, ∞. Hence it follows that from the base points P (0, 1, ∞) we can construct a *rational scale* of points $P(r)$, where r is any rational, positive or negative number. It may be added that these are the only points on the line which can be reached from the base-points by projective constructions, and it would be a good exercise for the student to prove what is not absolutely demonstrated in the book, that this deduction is free from ambiguity; for instance, suppose $P(x)$, $P(y)$, $P(x+y)$ have each been deduced from the base-points by a chain of projective construction, it is required to prove that *the same point*, $P(x+y)$, is derivable from $P(x)$ and $P(y)$ by the single operation of addition.

The net result of these considerations may be put (among other ways) in the following form. Suppose we have a tetrahedral frame of lines with a point given on each line distinct from the two vertices of the tetrahedron which it contains. Then on each of the six lines we can construct a rational scale, and hence, by projective constructions alone, arrive at all points which can be defined by four rational homogeneous coordinates. This rational projective space is not continuous: to fill up the lacuna, it will be necessary to assume the existence of one linear continuum of points, and apparently this will be also sufficient.

Staudt, on the other hand, gives his constructions as the definitions of the addition and multiplication of throws; and because the laws of algebra are satisfied, he deduces the possibility of assigning numerical values to throws. On the whole, Staudt's procedure seems the more scientific, but it is not a matter of much importance.

A propos of involutions, attention may be directed to the proposition on p. 223: "Any projectivity in a one-dimensional form may be obtained as the product of two involutions." This is very interesting, because it shows that although involution is, in the first instance, a derivative idea (as a special case of projective correspondence) it may ultimately be regarded as elementary.

To indicate how far this volume proceeds, it will be sufficient to say that chapter x. deals with pairs and pencils of conics in a plane, and gives the typical algebraic forms according to the elementary divisors of the discriminant; while the next, and final, chapter is on families of lines, and treats briefly of ruled quadrics, line coordinates, and linear congruences and complexes. It might, by the way, interest applied mathematicians to point out that if we suppose a unit force acting along a given line, the six homogeneous coordinates of the line may be taken to be proportional to the moments of the force about the edges of the tetrahedron of reference.

G. B. M.

THE NEW PSYCHOLOGY.

Manual of Mental and Physical Tests: a Book of Directions compiled with special Reference to the Experimental Study of School Children in the Laboratory or Class-room. By Prof. G. M. Whipple. Pp. xix+534. (Baltimore, U.S.A.: Warwick and York, inc., 1910.)

IS psychology to rank among the exact sciences? This is the question which is at once raised when we look into Prof. Whipple's volume. We are reminded of Kant's famous pronouncement that psychology never could be a science, because it was impossible either to apply mathematics to its problems or to perform experiments upon the minds of others. Kant's dictum is a classical instance of the danger of prophesying the impossible. In the book before us the mathematical treatment of mental measurements is discussed in the third chapter, and the rest of the volume is made up of more or less happily devised experiments upon the minds and bodies of other people.

Yet nobody knows better than the author himself how relatively slight actual accomplishment has been. The contrast between the position of the psychologist and that of the doctor, for example, is very great. An insurance company will decide quite serious financial questions on the report of a medical man whose tests give sufficiently good *average* results for their purpose. But the psychologist has not yet achieved a position of such confidence. He deals with far subtler problems, and it is no fault of his that we have not yet begun to consult him on the future of our children. He frankly confesses that he is not ready to render such positive service; and whilst on one hand we may fairly congratulate ourselves on the fact that a serious attempt is being made to arrive at a better understanding of mental phenomena, it would, on the other hand, in Dr. Whipple's words, be wrong to speak

> "as if a science of mental tests had already been achieved. . . . To make such an assertion is surely misleading, for . . . there is, at the present time, scarcely a single mental list that can be applied unequivocally as a pyschical measuring-rod."

There is no general agreement about procedure, and in many cases psychologists do not know exactly what it is they are measuring, such is the "astounding complexity, variety, and delicacy of form of our psychical nature."

It would, nevertheless, ill become professional students of the older sciences to speak in contemptuous terms of a younger brother who is so conscious of his own shortcomings. Psychology may have long to wait for its Newton, but in the meantime the effort to collect facts in a scientific way should surely meet with every possible encouragement. The "man in the street" has long recognised the existence of differences in the mental characteristics of his friends. He accepts them in much the same spirit as folk regarded the weather, until the meteorologist began that painstaking collection of data which is just beginning to bear scientific fruit. We have more words to describe these personal differences than we have for

the discussion of weather variations, but popular analyses are proverbially unsound, and the psychologist has in recent years attacked this problem of individual differences with vigour, ingenuity, and insight.

It is as presenting a survey of work in this direction that Prof. Whipple's book is to be regarded. Hitherto nothing of the kind has been available, and the author has rendered a capital service to English workers in this field by compiling from widely extended sources such mental tests as have been used with more or less success in the study of children. The tests are arranged in the order of the simplicity of the psychical processes involved. Beginning with those which concern physical and motor capacity, they pass through those which measure the various forms of sensory acuity, to others which deal with attention, memory, suggestibility, and close with the Binet-Simon tests of intellectual development. Each test is accompanied by a critical survey of work already done in regard to it, and an exhaustive bibliography. As a mere index to the literature of this branch of psychology, the book is of the greatest value. J. A. Green.

CULTIVATION OF THE LAND.

To Work a Grass Holding at a Living Profit, and the Cheap Cottage Problem. By H. B. M. Buchanan. Pp. vi+102. (London: Constable and Co., Ltd., 1910.) Price 1s. net.

Few movements of recent years have attracted greater interest than the migration from town to country that now plays so large a part in the life of the village community. Not only does the well-to-do man live further out into the country, but the humbler town-dweller is being enticed out; and the agricultural labourer, instead of drifting off unheeded to the town, finds all sorts of inducements held out to him to remain where he is. Small holdings are one of the most important developments of this movement, and they are encouraged with the twofold object of getting more produce out of the land and of bringing up the next generation in the country rather than in the unhealthier conditions of the town. It is arguable that the small holding is, *per se*, uneconomical, since the small holder cannot have the intelligence of the good farmer, or he would long ago have become a large holder; but there can be no difference of opinion as to the desirability of raising the next generation in the country. This social aspect of the question has to be kept in view in dealing with the rather bulky literature that has grown up on the subject.

Mr. Buchanan has taken an honourable part in fostering the new movement. He has studied small holdings from within, having made some on his own estate and carefully watched their development. Two classes of small holders he considers are likely to succeed: experienced people who supplement the profits of the holding by outside employment; and colonies working on cooperative lines directed by skilled supervision. The basis of their work must be the cultivation of the land; they are not likely to succeed in raising poultry, geese, cows, &c., on purchased food, however profitable the expert may find the business. And the weak link in all our cultivation is, in Mr. Buchanan's view, the management of our grass land. To this problem, therefore, he devotes a considerable amount of attention.

Grass presents a more difficult set of problems than any other crop. It is left down permanently; seeds of all kinds blow on to the ground, and may, if they can, germinate and grow, and finally oust some of the grass previously there. There is, in fact, a constant competition for existence among the various plants, and, in general, the poorer the soil, the larger the number of plants present. Artificial manuring, mowing, grazing, and grazing supplemented by concentrated foodstuffs, all modify the conditions obtaining, and favour some species that develop to the exclusion of others. The farmer's problem is to adopt those methods of treatment that shall in the shortest time and at the least cost enable the species he wants to crowd out those he does not want. In a certain empirical way, methods are known that will more or less do this, and Mr. Buchanan sets them out clearly and concisely.

The cheap cottage problem is intimately bound up with the small holding movement. The very large landowner may be prepared to put up cottages and let them at a rent that brings in little or no interest on the outlay, but Mr. Buchanan does not think these "charity cottages," as he calls them, will solve the problem. He gives plans and specifications of cottages at 500*l.* the pair that are suitable and comfortable, but as the rent has to be 4*s.* 6*d.* a week to make the outlay profitable, he arranges that a garden and pigsty can be included, the profits of which shall pay the rent. Suitable hints are given to the cultivator, and also to the owner of the estate.

The book will be found very interesting and suggestive not only to those concerned in small holdings, but also to the cultivator and to those engaged in agricultural education work E. J. R.

NEW BOOKS ON CHEMISTRY.

(1) *Introduction to Practical Organic Chemistry, including Qualitative and Quantitative Analysis and Preparations.* By Dr. A. M. Kellas. Pp. viii+204. (London: H. Frowde and Hodder and Stoughton, 1910.) Price 3*s.* 6*d.* net.

(2) *New Reduction Methods in Volumetric Analysis.* A Monograph. By Prof. E. Knecht and Eva Hibbert. Pp. x+108. (London: Longmans, Green, and Co., 1910.) Price 3*s.* net.

(3) *Introduction to General Chemistry.* By Prof. J. T. Stoddard. Pp. xviii+432. (New York: The Macmillan Co.; London: Macmillan and Co., Ltd., 1910.) Price 7*s.* net.

(1) The "Introduction to Practical Organic Chemistry" is divided into six sections. The first section deals with qualitative tests, the second with general laboratory operations; the third with preparations, the fourth and fifth with the analysis of specific compounds, and the sixth with ultimate organic analysis and molecular weight determinations.

Though the book contains very little that is original either in matter or arrangement (unless in its special adaptation to the syllabuses of certain examining bodies), there is, on the other hand, nothing which calls for adverse criticism. The laboratory operations are such as have appeared in half a dozen books on the subject. They are clearly and fully described and illustrated. There is also a useful appendix containing details of practical work presented for the preliminary science examination, part ii., of London University. We should be very sorry to follow the author in advising students wishing to carry the subject further to make an extended study of Lassar-Cohn's "Arbeitsmethoden" or Meyer's "Konstitutionsermittelung," both of them ponderous and useful, but incomparably dull and formidable, books of reference. Apart from this the book may be safely recommended to all students of practical organic chemistry.

(2) Dr. Knecht has collected in the form of a small monograph his various papers on the use of titanous chloride as a volumetric reagent. His method is so well known among analysts, and especially colour chemists, as to require no description, and its value has been fully recognised. The present volume should serve to extend its use by bringing it to the notice of a larger public, and by emphasising its remarkably wide application. Titanous salts, it may be added, are readily procurable, so that there is no obstacle in the way of their employment.

(3) "C'est le premier pas qui coute" is probably truer of text-books of chemistry than of other sciences. It is because authors will assume that chemistry is an exact science and that its principles are capable of precise definition that the opening chapters are frequently so unsatisfactory. To begin with definitions and generalisations is to court contradictions and inconsistencies at every turn. Here we have a volume by an obviously thoughtful and careful writer who attempts to define chemical and physical change. "These [physical] properties are always the same in all specimens of the same substance, whatever its source, when they are examined under the same condition," yet a few paragraphs further on we are told that the same metal may occur in a bright metallic or dull pulverulent form. Again, whilst cautiously stating that every *definite* chemical compound always contains the same elements in the proportion by weight, he says nothing about *indefinite* compounds, and adds rather recklessly that "with this constancy of composition goes a similar constancy in all of the properties which characterise the compound."

When the author has safely extricated himself from the rocks and shoals of his introductory chapters, he gets into smooth water, and the remainder of the book is plain sailing. We presume that "the first year's course" mentioned in the preface has reference to the college student; for it is certainly not a book for a beginner. The absence of all diagrams and experimental details and the use of technical terms without explanation would soon lead him into a labyrinth of difficulties.

J. B. C.

OUR BOOK SHELF.

British Ferns and their Varieties. By C. T. Druery. Pp. xi+458. (London: G. Routledge and Sons, Ltd.; New York: E. P. Dutton and Co., n.d.) Price 7s. 6d. net.

THE author of this book, who is well known as an enthusiast in the study and cultivation of British ferns, has succeeded in producing a work very useful to all fern-lovers. Hitherto it has been a matter of great difficulty for anyone to discover what name has been applied to a given form of any British fern, unless he has had access to some standard collection for comparison. This difficulty will now be greatly reduced by reference to the illustrations in this book, which consist of 40 coloured plates, 96 nature prints, and 319 others.

The first sixty pages are devoted to general considerations, such as the life-history of ferns, culture (including hybridisation), types of variation, and fern foes. The attempt to write these introductory chapters in popular language has, as is usual in such cases, resulted in some words being used in a sense differing from that in which they are applied in scientific works. For instance, on p. 15 the oosphere is referred to as "the incipient seed," and the antherozoids are stated to be "truly vegetative"; and on p. 27 the young plants are by preference termed "seedlings."

The remainder of the book contains detailed accounts of the British species, with short notes on their varieties and forms. The nomenclature usually adopted in British books has been retained on the ground that this work is intended "rather for the practical amateur than for the scientific botanist"; it is to be regretted, however, that synonyms are almost entirely omitted, even in the case of such a familiar one as *Nephrodium filix-mas.* The mixture of Latin and English names printed in the same type leaves one in doubt as to whether the final word forms part of the plant-name or is that of its describer or raiser, *e.g.* "*Pteris aquilina crispa cristata Druery*" (p. 221); in the case of *Polystichum pulcherrimum* (p. 211), these names are said to refer to the finder.

The wonderful variation in our native ferns is strikingly brought out in this book, which should stimulate many to become students of this very interesting group of plants, and to assist in solving the problems connected with variation.

C. H. W.

Motor Car Hill-Climbing Chart. To Show the Speed at which a given Motor Car can Climb any given Hill—to Show also the Gear upon which it can do so—and the Engine Speed in Revolutions per Minute. (London: Edward Stanford, n.d.) Price 1s. 6d. net.

THE "Motor Car Hill-Climbing Chart" consists of a card $5\frac{1}{2}$ by $3\frac{1}{2}$ inches, on the face of which there is a sliding card. The sliding card has a square hole in it covered by a transparent sheet. On this is drawn a brown curve representing the resistance due to average road and wind resistances at different speeds. Through the window three other curves, the forms of which have been determined by experiment, may be seen. These are of different colours, and are adapted to suit one each of the three gears. The sliding card can be set by means of a scale to a position corresponding to any gradient up or down. Then the intersection of the brown curve with one or other of the other curves shows which gear should be used, what speed the car should go, and the r.p.m. of the engine when the car is in good order. If the curves have been produced by experiment with the particular car, no doubt useful results will be obtained, and that most conveniently, but until all cars are alike it is difficult to see what use it will be on somebody else's car.

The Gyroscope: An Experimental Study. From Spinning-Top to Mono-Rail. By V. E. Johnson. Pp. 52. (London: E. and F. N. Spon, Ltd.; New York: Spon and Chamberlain, 1911.) Price 1s. 6d. net.

THIS is an admirable little book suitable from every point of view as a present for a boy with a mechanical turn of mind. As the extended title indicates, the properties of the gyroscope are illustrated by a series of experiments, always with a view to its application to a mono rail car. The reader is expected to be able to drill holes in metal and tap threads in them and perform simple constructional operations. He is thus encouraged to prepare his own apparatus and make each experiment as he goes along.

The originality of some of the experiments and the conclusions to be drawn from them, the home-made gyroscope, with the flywheel of a sewing machine as centre feature, and the general scheme of the book are all excellent, and any boy who works through the examples will find himself imperceptibly acquiring the gyroscopic sense, and he will greatly enjoy the process. One of the later devices illustrated is an electrically-driven monorail and gyrostat, for further details of which the reader is referred to the number of *The Model Engineer* in which it was first described. No doubt this is the apparatus that was shown at work at the last exhibition organised by *The Model Engineer.* C. V. B.

Simple Lessons in Nature Study. By J. O'Neill. Pp. 122. (London: Blackie and Son, Ltd., n.d.) Price 1s. net.

THIS book comprises about twenty-five lessons on plant characters and ten referring to animals; buds, the work of leaves, the dandelion, birds, the hedgehog, talks on tadpoles, are a few of the subjects discussed. It has been prepared for the use of teachers; as such it has no obvious merit, because it cannot be said to present simple facts and natural inferences in any new light, nor does it penetrate sufficiently deeply into the subject to impart the knowledge required for teaching.

Aphorisms and Reflections from the Works of T. H. Huxley. Selected by Henrietta A. Huxley. Pp. 86. (London: Watts and Co., 1911.) Price 6d.

MESSRS. WATTS AND CO. have issued these aphorisms and reflections of Huxley for the Rationalist Press Association, Ltd., by permission of Messrs. Macmillan and Co., Ltd. The price at which the book is now obtainable will, it is to be hoped, make Huxley's clear thinking and lucid expression known to a new circle of readers and send many of them to the complete works from which the apothegms are selected.

The Flight of Birds. By Giovanni A. Borelli. Pp. x+40. (London: For the Aëronautical Society of Great Britain by King, Sell, and Olding, Ltd., 1911.) Price 1s. net.

WE have here a translation of the section called "De Volatu" in the first volume of Borelli's "De Motu Animalium," first published in Rome in 1680–81. This is the first time this part of the seventeenth-century classic has been translated into English. The booklet will make an appeal to all who are interested in the conquest of the air.

Life Histories of Familiar Plants. By John J. Ward. Pp. xx+204. (London: Cassell & Co., Ltd., 1911.) Price 3s. 6d.

THIS popular edition of a book which appeared in 1908 should prove of service to teachers of nature-study and field botany. The first edition was reviewed in these columns on May 20, 1909 (vol. lxxx., p. 344), and the present issue remains unchanged.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

The Fox and the Fleas.

THE belief that the fox rids himself of fleas by the device to which Prof. Hughes has directed attention in NATURE is a long-established one. This is shown by the following passage from Allan Ramsay's "Gentle Shepherd," which appeared in the year 1725:—

"As fast as flaes skip to the tate o' woo,
Whilk slee tod lowrie hauds without his mow,
When he to drown them and his hips to cool,
In summer days slides backwards in a pool."

The language is the variety of English which prevailed, and of course still prevails, in North Britain. "Tate o' woo" means tuft of wool, "slee tod lowrie" means the sly fox, and "hauds without his mow," holds outside his mouth. A. N. MELDRUM.

Hamilton, N.B., April 10.

REFERRING to the letter of Prof. McKenny Hughes on the fox and the fleas, in NATURE of March 23, may I be allowed to say that I heard exactly the same story, several times over, in my youth, which means about fifty years ago? I must confess that I thought it had originated somewhere in Gascony, the home of Cyrano of Bergerac. It seems now to turn out to be true. If really authenticated, as Mr. T. Day appears to suppose it, it would be worth while to make its exact authentication known, as it may be looked upon as a most prominent proof of reasoning on the part of an animal.

Paris, March 24. T. S. GREY.

MANY years ago a few friends were chatting in Kirkby Lonsdale Vicarage, and one of us remarked that almost everybody had within his own knowledge some story that he could not expect his friends to believe. The vicar (Henry Ware, afterwards Bishop of Barrow) told us his story. He was coming out of the vicarage with Archdeacon Evans and the parish clerk, when they saw in the lime avenue in front of them a chaffinch fluttering up and down with the tip of its wing attached to one of the long pendulous twigs of a lime tree. The clerk got steps and a hook or something by which he pulled it down, and they found that the bird's wing was stuck, as they thought, by the honey dew to the leaf, while the play of the twig never let it get sufficient lateral pull to disengage it.

DE ANIMAL. SYLVES.

De dolofo ingenio Vulpium.

My story was that, when I was a boy, walking home along the banks of the Bawddwr, which was then frozen over, I saw a trout through the clear ice and took a shot at it with a stone. The stone made a small hole in the ice, through which the trout jumped out. I thought that the pressure on the ice due to the impact caused an uprush of water, which caught the trout as he darted away and carried him out head first.

It may not have been altogether the honey dew that stuck the bird's wing to the leaf, and the mechanics of my trout's leap may be better explained, but the stories are true.

So in the often repeated and much discussed story of

the sea-serpent: whether we refer what was seen to long lines of ducks now dropping out of sight in the trough of the wave, now rising in thick coil over its crest; or to water-logged baulks of timber with seaweed hanging like a mane about the ends, which were protruded or submerged with the rise and fall of the waves; or whether we accept Günther's explanation of the best authenticated case on record, which he described as a sperm whale attacked by an octopus, the dimensions of which he calculated from known examples; we admit the stories and discuss only the explanations, which in these last cited cases must differ so much.

So for Mr. Day's story of the fox and the fleas; we may examine it from several points of view. If it is a true natural history story it is extremely improbable that Mr. Day's was the first and only recorded fox who showed this instinct, or, as Samuel Butler would call it, "memory"; and, thanks to many friends, I can give more or less clear references to previous observations of the same kind. Mr. Nichols tells me that he has heard it mentioned as a story current among Celtic people—likely enough, as they are chiefly pastoral and close observers of natural phenomena. Mr. Grey in his letter, which by your courtesy I have seen, thinks he remembers it as belonging to Gascony. But the most important contribution to the discussion, so far, is a reference sent by my friend and pupil Mr. Frank Barclay, which I have verified in the university library.

Olaus Magnus, writing in 1555, says:—

"Praeterea cùm pulices habet, fasciculum mollis foeni ore accipit pilis involutum, seque paulatim posterius inchoando in aquam mergit, ac totum corpus, ut pulices aquam fugientes, ad caput ascendant. Deinde caput immergit, ut in foenum fugiant; quo facto, foenum relinquit in aqua, et mox enatat."

Besides, when he has fleas he takes in his mouth a bundle of soft hay rolled up in hair, and gradually immerses himself in the water back end first, and then his whole body, so that the fleas, trying to escape from the water, may creep up to his head. Then he draws his head under water that the fleas may be driven to take refuge in the hay, and when this has been done he lets the hay go in the water, and forthwith swims out.

The amusing figure which Olaus Magnus gives in illustration of the various cunning devices of foxes which he describes has been admirably reproduced by Mr. Edwin Wilson.

Foenum pilis involutum is not quite clear. Mr. Day does not remember anything about hay, and in Olaus Magnus's picture there is nothing like hair or wool shown; but the word is late Latin, and may be used as loosely as the modern "pile," which is either hair or the soft, fluffy nap taken off the surface of cloth. That is, however, unimportant. But I was given an interesting fact in corroboration of the probability that the fleas would readily betake themselves to wool. Miss Parsons, of Horseheath, a shrewd observer of natural phenomena and collector of folklore, told me that it was a common opinion among farm people that if poultry and poultry houses were infested by fleas the best way to get rid of them was to drive a flock of sheep among them, as every flea would take to the wool.

There is another point to be considered—I do not know that a fox is an animal much troubled by fleas. It may be that the curious procedure on the part of Mr. Day's fox was not a thing of common occurrence, but only when the animal had the misfortune to be suddenly attacked by an abnormal number; for great swarms of fleas do suddenly appear, not only on certain individuals or groups of animals, but on walls and wooden partitions. Some of your readers will remember the story of Dr. Michael Foster's dog and the fleas, which he carried in from a wall outside the house. I have myself seen the wooden frame of a hot-bed covered with them, and sometimes a hedgehog carries an enormous number.

A fox's calling takes him occasionally to hen houses, and commonly to earths frequented by hedgehogs, and he might therefore sometimes have to take strong measures to get rid of the excessive number of fleas he had carried from such places.

Mr. Day vouches for the truth of the story as I gave it in your issue of March 23, except that the hurdles and straw were put up to shelter him and his father, and not to protect sheep and lambs, for it was in July (1843).

The fox went into a deep part of the small stream that runs by Mob's Hall into the Rhee or Cam near Thistly-ground Farm, about a mile west of Guilden Morden.

T. McKENNY HUGHES.

Ravensworth, Brooklands Avenue, Cambridge.

The Radiation producing Aurora Borealis.

As is well known, Prof. Birkeland has put forward the hypothesis that aurora borealis and magnetic disturbances are due to an "electric radiation" coming from the sun. The numerous observations, partly from the regions near the auroral zone, treated by Birkeland in his work "The Norwegian Aurora Polaris Expedition, 1902–1903," as well as the theoretical work by Prof. Störmer, have shown that this hypothesis in a very satisfactory way accounts

for the characteristic properties of aurora and magnetic disturbances, as well as regards occurrence as with respect to distribution in space relative to the earth.

The phenomena of aurora and magnetic storms, however, show a great variety of forms, and further knowledge will be required until we are able to follow every single phenomenon into details. From the point of view of Birkeland's hypothesis, it will be the next step to determine more definitely the properties of those "electric rays" which in the various cases produce the aurora and magnetic storms.

From the position of the auroral zone, Birkeland has already (*Comptes rendus*, 1910) estimated the average stiffness of the rays as measured by their deviation in a magnetic field, and he found that the rays are ten times as stiff as ordinary α rays.

The question would now naturally suggest itself, Is the "electric radiation" of the type of β rays consisting of corpuscles or of the type of α rays consisting of atoms? It is my intention in this note to direct attention to certain points which may guide us regarding this question.

As is well known, the law governing the absorption of the rays by matter is very different for the two types. The α rays penetrate matter in nearly straight-lined orbits, and only a very small fraction is scattered to any appreciable amount. The velocity of the α particle gradually diminishes as the particle passes through matter, and for a certain velocity it loses its power of ionising the mole-

cules of a gas and to produce photochemical action. The number of ions produced per unit length along the path of the α particle has its maximum very near the point where it loses its ionising power. The β particles, however, are almost completely scattered in the first thin layer of matter, and inside it the radiation broadens out in all directions, and any trace of the direction of the impinging rays is soon lost.

In the aurora, according to Birkeland's theory, we are actually examining the luminosity produced when the electric radiation strikes the upper strata of the atmosphere, and from the form and structure of the luminosity we should be able to examine the way in which the solar radiation is absorbed by matter.

One of the most conspicuous forms of aurora are the draperies, of which an illustration is given in the accompanying figure. We notice the straight-lined structure. That the draperies are formed by something coming towards the earth from outside will be evident to all who have witnessed their formation. On March 27, 1910, the writer had the opportunity of examining a most brilliant aurora from the mountains of "Jotunheimen." Brilliant draperies were formed, and they could be seen actually falling down in the direction of the streamers, one bundle adding itself to another in rapid succession so as to form long spirals and bands. Now the structure of the luminosity is just as would be expected if the draperies were formed by a type of rays showing an absorption like that found for the α rays. Looking at the luminosity along the transverse streamers, we shall always notice that the intensity gradually increases downwards, but stops all of a sudden, just as it is found for the ionisation produced by an α particle along its path.

I do not mean to say that it is exactly α rays or charged helium atoms which produce draperies, but I think that the similarity in absorption strongly points to a similarity in type of radiation—in other words, that the rays producing the draperies are of atomic size and carry an electric charge.

The fact that the draperies occur mostly on the evening and night side of the earth should, according to the law of the magnetic deflection, require a negative charge of the rays; but such rays may well be possible, for, as we know, Sir J. J. Thomson has found that accompanying the positive rays in a vacuum tube there are other rays formed by atoms, but carrying a negative charge.

In view of the fact that a number of the same spectral lines are found in the corona and the aurora spectrum, which belong to the rare gases, it would be natural to suppose that these inert gases, *e.g.* argon, neon, xenon, krypton, helium, and possibly coronium, are forming the carriers of the "electric radiation" producing the draperies.

The existence of such radiation does not in any way exclude the existence of corpuscular rays; these may be the cause of the auroral "arch," which has just the diffuse appearance to be expected from the law of absorption of the β rays. Further, the magnetic disturbances may to a great extent be due to radiation of the β-ray type.

The Velocity of Earth Movements caused by the Messina Earthquake.

I AM deeply indebted to Prof. J. Milne, F.R.S., who, in NATURE of March 23, did me the honour of directing the attention of scientific men to my memoir on the velocity of earth movements caused by the Messina earthquake. As the notice contains some remarks on my work which require a little explanation, I beg to be permitted to state my views here.

According to some seismologists, the position of the hypocentre is at the intersection of an asymptote to Schmidt's hodograph, with a vertical ordinate drawn through its apex. It seems to me, therefore, that the absence of any measurable flexure in the curves may really mean that the hypocentre of the Messina earthquake was very shallow. That is, however, a matter of opinion about which seismologists can easily be divided, and I have no desire to insist on this subject.

Prof. Milne assumes that I divided the large-wave phase of the seismograms into three parts, called L_1, L_2, L_3, being L_1 the commencement of maximum motion, L_2 the maximum movement itself, and L_3 the phase which travels the slowest. He adds that if this is to be accepted as a definite and recognisable phase in a seismogram, there seems to be no reason why we should not also accept many other phases, which may be indicated by the letters L_4, L_5, L_6, &c. The remark is of interest, but I deserve neither praise nor blame for the division of the large-wave portion of seismological registrations. Prof. Milne well knows that the division of the principal portion of a seismogram into six groups was done by Prof. Omori, analysing the registrations obtained at Tokio, and such a division is now accepted by almost all seismologists. In my memoir, L_1 indicates the commencement of the initial phase; L_2 and L_3 are respectively the commencements of the slow-period and of the quick-period phases of the principal portion of the registrations, according to Prof. Omori's division.

Instead of considering as a whole the large-wave phase, which involves some uncertainty (as often the commencement of the principal portion is assumed to be on Omori's initial phase and at other times the commencement of the same principal portion is referred to the slow-period phase), I tried to distinguish in all seismograms the first three groups of the large-wave phase, L_1, L_2, L_3. I am not dissatisfied at having done this, because I have obtained some results which I think are not without importance for physical seismology.

I conclude by expressing my warmest thanks to Prof. Milne for his notice and for the valuable article on the necessity of restoring the Messina Observatory contributed by him to NATURE of February 16.

Messina, March 30. G. B. RIZZO.

FROM THE NIGER TO THE NILE ACROSS AFRICA.[1]

DR. KARL KUMM (whom, from the indirect statements made in his book, we take to be of Swiss origin, and who now seems to be for all practical purposes an Englishman) assisted to found the Sudan United Mission in 1907–8. This mission was expressly intended to work in the Nigerian and Egyptian Sudan to counteract the Moslem advance, and Christianise the pagan tribes of negroes not as yet influenced by the Muhammadan religion. His previous acquaintance with Africa (according to the statements made in his "exordium") has been considerable. In 1899 he had visited "the southern oases of the Libyan Desert," and had travelled a considerable distance on the way to Darfur. In 1901 he travelled in Nubia. In 1904 he journeyed from Tripoli southwards into the mountainous region north of Fezzan and studied the Hausa language. In 1904–5 he led an expedition of investigation into northern Nigeria. In the two following years he visited America and South Africa to arouse interest in his mission and secure data as to the advance of Islam in the direction of the Zambezi. On his return from South Africa he visited Portuguese East Africa, Mombasa, and made a hasty journey to Uganda.

In October, 1908, he left Liverpool with seven missionaries of the newly formed Sudan United Mission to visit or to found mission stations in northern Nigeria, and establish a home for freed slaves. He further intended, if practicable, to cross Africa along the border-line between Islam and paganism.

The book under review is the result of this last journey, which extended from Forcados, at the mouth of the Niger, along the course of the Benue to the Musgu country on the Shari, thence up the Shari River to Fort Archambault, and from that point along the line of water-parting (more or less) between the Shari, the Congo, and the Nile. He emerged into some-

[1] "From Hausaland to Egypt, through the Sudan." By Dr. H. Karl W. Kumm. Pp. xiv+324. (London: Constable and Co., Ltd., 1910.) Price 16s. net.

thing like civilisation at Shambi, on the White Nile, midway between Lado and Fashoda. From Lado he descended the White Nile to Khartum, and thence journeyed home through Egypt. From the point of view of travel and endurance, it was the latest and not the least noticeable crossing of Africa; though to the thinking of the present reviewer, one of the most remarkable achievements in crossing Africa was that accomplished by Mr. Walter Savage Landor a few years ago. This last-named traveller, in ordinary clothes and an ordinary hat and boots, armed with a walking-stick, and attended by one or two faithful Somalis (as a nucleus), quietly walked the greater part of the way across Africa at its very broadest, from east to west, from Somaliland to Senegambia. Mr. Landor would seem to have been somewhat shabbily treated by the geographical societies of the world in the relatively slight recognition which followed his feat. Apparently the reason for this is the same cause as that of the somewhat unkindly reviews of Dr. Karl Kumm's book, which have recently appeared in one or two journals, namely, that the mere traversing of Africa on foot, or by any other means of progression available, counts for very little unless such a journey is accompanied by the gathering of new and important information regarding the geology, geography, zoology, botany, or anthropology of the country traversed.

FIG. 1.—A Sara-Kabba woman carrying a plate in her lips. From "From Hausaland to Egypt."

No doubt there is some excuse for this point of view. But without reopening for the moment the question of Mr. Landor, the disparagement of Dr. Kumm's book seems a little harsh. *La plus belle fille ne peut donner que ce qu'elle a.* Dr. Kumm, perhaps, is most noteworthy (from the point of view of a biologist) as a collector of butterflies and moths. He managed to bring home 250 specimens of Lepidoptera, which have been named at the British Museum, and these are illustrated in the work under review by a selection of noteworthy forms very beautifully produced in colour, apparently by photography. So far as can be gathered from the book, none of these forms is completely new to science, but not a few of them are new as objects of wonder or beauty to the average reader.

A little further information is given regarding the zoology of these southern Sudan regions. A pair of horns of the variety of the Cape buffalo, found in the Shari valley and Lake Chad regions, illustrates the local Chad race of buffalo, known to us, however, since the early part of the nineteenth century. Dr. Kumm mentions that the young buffaloes of this variety are red in the colour of their hair, but become perfectly black when full grown. From the Shari valley he brought back the portion of the skull of a giraffe, showing in the two principal ossicones the beginnings of an embranchment, a most interesting feature as evidencing the latent tendency in this group (with which, perhaps, the Pronghorn is very distantly allied) which led in Miocene times to such results as the extraordinary branched antlers of the Sivatherium. This same Shari giraffe exhibited an exceptional development of the ossicone on the nasal bones between the eyes. Instead of being a mere bump, it rises to a considerable knob with an attenuated stem. Dr. Kumm also shot a rhinoceros in the Shari valley, an interesting fact as serving with other scanty information to show that the range of the rhinoceros does extend across west Central Africa to western Nigeria. Until recently, no proof had been advanced to show that the rhinoceros (unlike the zebra) was found west of the White Nile; though there is, of course, the tradition that the Romans, in their abortive expedition to Lake Chad about the year 21 A.D., entered a region on the outskirts of the Sahara Desert which swarmed with "unicorns." Dr. Kumm also thinks that he has discovered a new species or variety of crocodile, in which the bluish-black markings on the scales (present in the Nile and Slender-nosed crocodiles) have an exaggerated development, and form regular, blackish, vertical bands round the body. But this discovery is only an assertion backed up by a sketch from memory.

FIG. 2.—Horns of Shari-Chad Giraffe. From "From Hausaland to Egypt."

In Appendix A, Dr. Kumm gives some proverbs from the Beri-beri language, but we are not told (so far as I can gather) what is the geographical location of this speech. He supplies, further, a vocabulary of Bagirmi words, which, in view of Barth's admirable study of that language, is not a striking novelty. His vocabulary of Sara is more useful, though that speech of the very heart of Africa has already been illustrated by the French. Quite new, or at any rate, very nearly so, are his vocabularies of Nilim and Korbal of the Shari region. He also gives a few words of Sango, a language of the Upper Mubangi. The photographs illustrating the book are for the

most part of only tolerable interest and appositeness; the drawings which supplement the photographs are exceedingly bad: one wonders that the publishers could have inserted such. Amongst the more interesting illustrations is that of a Sara-Kabba woman, with her lips expanded artificially into something like a duck's beak. This method of deforming the lips seems to be a very old one amongst the negro race, and to have existed in ancient times in the westernmost parts of Nigeria. From the very heart of Africa, where Dr. Kumm came across it, it extends sporadically to the region between the Albert Nyanza and the Upper Congo; then, after another long gap in distance, reappears in parts of German East Africa, and attains a notable development (described by Livingstone) in the regions between Lake Nyasa and the coast.

Dr. Kumm gives a chapter on the anthropology of the Sudan tribes, which contains some new information, and especially some interesting illustrations of the many different methods of skin mutilation on the face (cicatrisation). He writes, however, much too freely about "Bantu," ascribing to the Bantu group of African people many tribes which have absolutely nothing to do with that language family. Although the conventional "Bantu" physical type is associated mostly with peoples of the Upper Congo of the lake regions and of South Africa who happen to speak Bantu languages, it is also to be met with elsewhere in West and Central Africa amongst tribes quite outside the Bantu language field. It short, it is better to drop the use of the term for any other but linguistic classifications.

H. H. Johnston.

THE NĀGAS OF MANIPUR.[1]

THE monograph before us, descriptive of the Nāgas (included in the Tibeto-Burman group of races), is issued by the Government, Eastern Bengal, as one of the series which already includes volumes on the Khasis, Meitheis, Mikirs, and Garos. Mr. Hodson's survey extends only to the branch of the tribe settled in Manipur, numbering about 100,000 out of a total population of 162,000 in British India.

As regards social organisation, the clan, an aggregation of households, forms the permanent political unit. the tribe being only a group of clans with little or no solidarity. The only tribal bond appears in the enforcement of common taboos of food and seclusion, and in the rule that a man must not marry a woman

Photo. E. J. Mitchell.

Mao Nāgas. From "The Nāga Tribes of Manipur.

whose speech differs from his own. This is due to the inhospitable character of the land and to the ferocity of its inhabitants, facts which also affect the linguistics. As Dr. Grierson has shown, this type of monosyllabic language, possessing no literature, with a floating pronunciation, and a number of loosely used prefixes and suffixes, being necessarily subject to rapid change, emigrants settled at a comparatively short distance develop a dialect unintelligible to members of the parent village. This absence of tribal organisation adds greatly to the difficulty of bringing these wild highlanders under control.

The Nāgas combine with a fairly advanced material culture many barbaric practices. While part of their farming is on the Jhum system, that is to say, the periodical burning of patches of jungle and sowing the seed in the ashes, they also possess terraced fields

[1] "The Nāga Tribes of Manipur." By T. C. Hodson Pp. xiii+212. (London: Macmillan and Co., Ltd. 1911.) Price 8s. 6d. net.

irrigated with water brought from considerable distances along skilfully aligned channels. They demarcate their village boundaries and recognise rights of property in land. They are skilled in weaving, make fairly good pottery, extract salt from brine wells, work up imported iron into weapons and implements, and are adepts in mat and basket weaving. Still, in spite of these advances towards civilisation, they practised up to quite recent times the brutal custom of head-hunting. As connected with their funereal rites this may be piacular, propitiatory, or both. It seems reasonable to suppose that, like the Wa of Burma, they procure heads in the hope that the soul of the victim will accompany his skull, and that when hung up in the house of its possessor this will act as a guardian against the powers of evil, the skull of a stranger being preferred, because the ghost does not know its way about, and is less likely to wander. Mr. Hodson has done good service in pointing out how the custom is connected with the blood feud, with funerary rites and eschatological beliefs, and that it has a social side as a proof of fitness for initiation into the tribe. Hence it is often encouraged by women, who laugh at young men appearing at the village festivals without the decoration which marks the successful warrior.

Mr. Hodson's careful review of the tribal and village customs, particularly the institution of taboos and the use of the communal house for males, superstitions, and religious beliefs, a survey largely based on personal intercourse with the tribe, forms an important contribution to the ethnology of India.

THE PENNY: A SUGGESTION.

DEAR old penny! You have been with me all my life. You were the first present I ever had, and when I was young your potentiality was great. You would buy everything a boy required—peg-tops, jam tarts, kites, marbles, or a bun. As I grew older I recognised that your purchasing power did not keep pace with my desires. Still, you do something—you give me a paper, a box of matches, or carry me long distances on trams or buses. With two or three pennies in my pocket I feel armed against emergencies. You will dry an urchin's tears or give comfort to a beggar. You have been and still remain a friend to young and old.

But with all your virtues you have still some drawbacks. I think you are susceptible of great improvement.

The ordinary person likes you in twos or threes, but in quantity he calls you "coppers." When in this form, the young lady in the shop frequently apologises —not for you so much, as for her inability to represent you by some other coin.

Forty-eight coppers, so says the law, weigh one pound; but nobody, whatever his vocation may be, cares to carry a pound, whether it be represented by forty-eight pennies or a lump of brass in his pocket. Not only would they weigh him down, but possibly they might spoil his figure. From the legal definition you should weigh one-third of an ounce, or 145·8333 grains. The latter number frightens me; it is indefinite and without end. It means nothing for common use. To carry about a weight which cannot be used to weigh anything in particular, not even a letter, is not practical. It is silly. If our penny could be made to weigh a little bit less but remain commensurable with an ounce, even if a hole was bored through its centre to reduce its weight, which would tell you what it was by its feel, the Chancellor of the Exchequer would, by the saving in metal, certainly be possessed of wealth equal to the fees of many Baronetcies. The public would have less load to carry, and rich and poor would have in their pockets a useful standard of weight.

As I am now finding fault, let me next ask whether you measure anything in particular. In your modern form, so far as I know, there is as little respectability in your dimensions as in your weight.

A penny is one out of a number of little discs that can be economically stamped out of a sheet of bronze. We are told that a bit of metal goes through rolls, which are so wonderfully adjusted that the resultant strips or "fillets" do not vary more than 1/10,000 part of an inch in their thickness. This suggests that the authors of the penny wished it to possess an accuracy bordering on the supernatural. But the subsequent punching, pressing, and milling has apparently done much to destroy their good intentions.

When you, little penny, entered the world, you were bright and shiny, with all the lustre, and colour of burnished gold; but your guinea-like look never lasted more than a few short weeks. You quickly became the microbic-covered old brown copper. You look round, you are supposed to be round, but are you really round?

Many times per day somebody or other wishes to draw a circle, puts you on a piece of paper, and scratches a pencil round your edge. Now and then the housewife puts you on a piece of linen to mark out buttonholes or points for decoration. The results look excellent, and satisfy many purposes, but a pair of callipers show that you have more than one diameter. The least diameter of our world runs from the north pole to the south, but if the north pole of a penny is Britannia's head and the fringes of her skirts the south, this is your longest diameter. Poor old penny, your dimensions have been made opposite to those of the world in which you circulate. The world is world-shaped, and you are penny-shaped. You only possess an average diameter, which is not an inch or an inch and a quarter, neither does it appear to be related to any everyday unit of linear measure. Your dimensions, like your weight, suggest an oversight on the part of your creators. You are lopsided and measure nothing in particular.

As you exist at the present day you measure a tiny little bit more than one inch and one-fifth. Why "the tiny little bit" exists, I and my friends connected with minting cannot tell. Knock it off, and the Exchequer would increase its capital without extra taxation, and five pennies would measure exactly six inches.

But reformation should go still farther, and the diameter of a penny, if possible, be made to measure something more definite by itself. If the halfpenny, which does measure one inch, stands in the way, do not disgrace it, but reduce it to another standard.

Our poor dumb friend, not only because it neither possesses a useful weight or measure, has been compelled to take a back place in numismatic competitions, but it has had to put up with a bit of extra weight in the form of an inscription. On one side of our penny we see a statement in abbreviated Latin which tells us that the Ruling Monarch is a defender of the faith. With this the penny gives us something to think about both day and night, and to many the statement may be regarded as in keeping with its weight and measure. On the reverse, we see a brave-looking, long-limbed lady sitting on a chariot, one wheel of which appears to be elliptical. I have been quite curious about this personage, and with the help of a magnifying glass have compared her face as shown on pennies and halfpennies. As a result of my examination I conclude there are at least two types of Britannia. The aristocratic, with a Grecian nose, and the democratic, with a *nez retroussé*. Possibly

the differences may be due to pressing, punching, or to wear and tear.

Therefore you are, dear old penny, from my point of view simply a token, without definite weight, definite dimensions, and with a variable expression.

The Spanish "penny" is marked ten grammes, and it also reads 100 pieces make one kilo. The "halfpenny" weighs 5 grammes, and, like the larger coin, is largely used for purposes of weighing. These coins also have useful dimensions.

If Britannia could be induced to sit a little more forward on her shield, with this and other slight adjustments, the penny would have a definite centre of gravity, and be of use as a plumb-bob, or as a pendulum in our board schools. With properly spaced milling on its edge, pennies could be used by Boy Scouts as angle measurers or rough protractors. When drawing plans, with one penny, and another to buy a compass, he could tell the time, or without a compass and with a watch he would know his bearings. With a piece of thread, a pebble for a weight, and a penny a clinometer could be made.

Whether any of these suggestions could possibly be carried out in practice remains for the consideration of the controllers of our coinage. A penny has had an up and down time of it. It has been altered often, and why not once again. The Romans possibly were too proud to accept small change, which, when handed to them, they flicked off the counter with the back of a finger, remarking "Romanus sum." At all events Roman coins seem to have been scattered over countries where Romans once resided, and now their coins are among the most common evidences of their former occupation. Six hundred years ago, when the penny was made of silver, it would pay a wage or buy a horse. Now it is only a little brown token. If the Chancellor of the Exchequer could see how to cut off "the little bit," make "the little hole" and use a less expensive metal the penny would be reincarnated, become the admiration of the world, taxation would be relieved, and Lloyd George worshipped. But do not forget to treat other tokens as you would the penny. Make them more cheaply and increase their usefulness.

John Milne.

THE BRITISH SCIENCE GUILD.

The fifth annual meeting of the guild was held at the Mansion House on April 7, under the presidency of the Lord Mayor. There was a fairly good attendance, and the number of well-known leaders in the field of technical and scientific education was large. Sir William White presented the annual report, and referred to the progress made during the year in various directions. Of the special activities of the guild, he mentioned the work of the subcommittees upon agricultural education, the proposed museum at South Kensington for the physical and mechanical sciences, medical education, and the relation of the Imperial College of Science and Technology with the University of London. From the annual report itself we learn that committees have also been investigating the problems involved in the conservation of natural sources of energy and the coordination of charitable effort. The guild has further benefited science and the community by its successful action in regard to the site of the Solar Physics Observatory; the existence of the science section at the Japan-British Exhibition, and the inclusion of a similar section in the plans for the forthcoming Coronation Exhibition, are also in large measure due to the guild's influence.

The features of the year's progress which Sir William White emphasised were the improved attitude of the Government towards agricultural research, and the greater readiness of Government departments generally to seek the advice of highly qualified men of science. In certain instances this readiness led to the appointment of consultative committees, which were acting in an advisory capacity to several departments. At the same time, Prof. R. A. Gregory's report showed how much more was being done in other countries to promote research. The organisation of the Canadian Committee has made good progress, and its first annual report has been issued. The spread of evening classes and the movement in favour of continued education are hopeful indications of the public recognition of the value of technical instruction.

Lord Haldane thought that the technical education which was at present being given in England was underrated. In higher education, in the application of science to industry, Germany had marked features which we did not possess; but evening schools and classes connected with the universities or great technical colleges were little known in Germany. Technical teaching had developed in a very striking way in London and throughout the United Kingdom. It was not without result. The quality of British goods commanded the respect of the world. Science was present in every corner of the Sheffield factories in which engines of war—offensive and defensive—were being constructed. Our Government was a very unscientific-looking machine, but it was being substantially and rapidly improved every year. There was far more intercommunication between various Government offices than was generally supposed. He hoped to see remarkable developments before long in the domain of public health.

We cannot refrain from expressing our regret that Lord Haldane should have dwelt so strongly on the merits of our evening-class system without qualifying his praise of this system by some mention of its inevitable shortcomings. The Technical Education Committee of the guild views the matter in a different light. This committee presented a very valuable report, and we quote from the last sentences preceding the recommendations which it contains:—

> Most of the technical instruction carried on in Great Britain is evening-class work. The committee, however, are strongly of opinion that day work is of infinitely greater value than work done in the evenings, when neither instructor nor student can possibly be at their best; consequently, evening work cannot be compared for thoroughness and efficiency with such day-class work as is done in the German, and in some of our higher, technical institutes. *Until this is recognised, it is impossible for this country to expect to compete technically with other countries.* (The italics are our own.)

There are valuable contributions appended to this committee's report by Dr. H. T. Bovey, Prof. Meldola, Dr. Pohl, Prof. Gregory, and Prof. Perry. The last-named awards an overdue meed of praise to the too-belittled work of the Science and Art Department, and has a word of encouragement for workers in evening classes, but he adds a strong appeal to employers to allow apprentices to attend science classes "*during the regular working hours*" (the italics are Prof. Perry's). It is evident from these reports that the guild is doing more than interest public men and impress them with the importance of scientific method, for through its committees it is doing the spade-work essential to the conversion of aspiration into practice. It is to be regretted, however, that no mention is made of the Education (Choice of Employment) Act which was passed in November, 1910. Though this may appear to be a very modest piece of legislation, it may well prove to be the starting point of national and

local systems for fulfilling one of the great aims of the guild, viz., organising the training of the youth of the country for industries and citizenship.

We hope that Lord Haldane will add the influence of his personal prestige to the authority of the president of the British Science Guild, so that the need of developing a *higher quality* of technical education in this country may be impressed upon local administrators and the general public. No better text for a discourse upon this theme need be sought than the sentence quoted so appropriately in the annual report from one of the last public utterances of King Edward VII.:—

As time goes on, I feel more and more convinced that the prosperity, even the very safety and existence, of our country depend on the quality of the scientific and technical training of those who are to guide and control our industries.

G. F. D.

The following gentlemen were elected as vice-presidents of the Guild at the annual meeting:—the American Ambassador, Sir Thomas Barlow, K.C.V.O., F.R.S., Sir Lauder Brunton, Bart., F.R.S., Sir Ernest Shackleton, C.V.O., and Major O'Meara, R.E., C.M.G.

The membership of the Guild, including the Canadian Branch, has increased from 793 at the end of 1907 to 872 at the end of 1910; of these, 28 are life fellows, 58 fellows subscribing annually, and 425 life members. In addition to these, there are 7 members belonging to the Australian Branch, of whom 5 are life members.

The following were elected to form the executive committee for 1911–12; the names of new members are printed in italics:—*President*, Rt. Hon. Viscount Haldane, K.C., F.R.S.; *hon. treasurer*, Rt. Hon. Lord Avebury, P.C., F.R.S.; *hon. assist. treasurer*, Lady Lockyer; *vice-presidents*, *Sir Thomas Barlow, K.C.V.O., F.R.S.*, Sir David Gill, K.C.B., F.R.S.; *chairman of committees*, Sir Norman Lockyer, K.C.B., F.R.S.; *vice-chairmen of committees*, Sir Hugh Bell, Bart., Hon. Sir John Cockburn, K.C.M.G., Prof. Meldola, F.R.S., Sir William Ramsay, K.C.B., F.R.S., Mr. F. Verney; *other members*, *Mr. Wm. Phipson Beale, K.C., M.P.*, Dr. G. T. Beilby, F.R.S., Dr. Bovey, F.R.S., Sir Edward Brabrook, C.B., *Mr. Harold Cox*, *Prof. Farmer, F.R.S.*, *Sir Luke Fildes, R.A.*, Surgeon-General Sir A. Keogh, K.C.B., Prof. A. Liversidge, F.R.S., Mr. A. Mosely, C.M.G., Mr. C. Freeman Murray, Prof. J. Perry, F.R.S., Sir Boverton Redwood, Mrs. W. N. Shaw, Mr. Carmichael Thomas, Dr. A. D. Waller, F.R.S., Colonel Sir John Young, C.V.O.; *hon. secretaries*, Sir Alex. Pedler, C.I.E., F.R.S., Dr. F. Mollwo Perkin.

NOTES.

Dr. L. A. Bauer, director of the Department Terrestrial Magnetism of the Carnegie Institution of Washington, sailed from Vancouver, B.C., on March 24 on a trip of inspection of the non-magnetic yacht *Carnegie* at Colombo, Ceylon, where she is due to arrive some time in June next. *En route* Dr. Bauer will call at the magnetic observatories at Melbourne and Christchurch.

We regret to see the announcement, in *The Times*, of the death of Mr. Charles du Bois Larbalestier, a leading authority on lichens, to whom the last edition of Leighton's "Lichen Flora" was dedicated; and also of Mr. J. S. Slater, for many years principal of the Civil Engineering College, Sibpur, near Calcutta.

The following have been elected by H.H. the Prince of Monaco the members of the first council of the new Institute of Human Palæontology in Paris:—MM. Salomon Reinach, Boule, Verneau, Cartailhac, Capitan, Villeneuve, for France; Sir Ray Lankester for the British Isles; Prof. von Luschan for Germany; Prof. Hoernes for Austria-Hungary; Prof. Issel for Italy, and Prof. G. Retzius for the Scandinavian countries.

Dr. S. F. Emmons, an American geologist of distinction, died at Washington on March 28. He was born in Boston in 1841, and, after graduating at Harvard, studied at the Schools of Mines in Paris and Freiberg. He had been connected with the U.S. Geological Survey since 1867, and was a prolific author of geological publications, especially reports on explorations in the Rocky Mountains and Colorado.

Dr. D. Mawson, whose paper on the Australasian Antarctic Expedition, read before the Royal Geographical Society on Monday, appears elsewhere in this issue, announced to the society, towards the close of his address, that the Commonwealth Parliament will probably be asked by the Government to vote a sum of 20,000*l.* towards the expenses of the expedition. The council of the Royal Geographical Society has decided to contribute the sum of 500*l.* to the expedition.

Dr. J. S. Flett has been appointed to succeed Dr. J. Horne, F.R.S., as assistant in Scotland to the director of the Geological Survey. Dr. Flett is a graduate of Edinburgh University, where he was Baxter Scholar, Falconer Fellow in Geology, and a Heriot Research Fellow. He was for four years lecturer on petrology in the University, and in 1901 joined the Geological Survey. In 1903 he was appointed petrographer to the Survey. After the West Indian eruptions in 1901, he was sent out with Dr. Tempest Anderson by the Royal Society of London to report on the volcanic phenomena. He has published many scientific papers dealing principally with the volcanic and metamorphic rocks of the British Isles, and he has contributed largely to the memoirs of the Geological Survey, not only on Scotland, but also on Cornwall and Devon. For scientific research he was awarded the Neill medal by the Royal Society of Edinburgh (1902) and the Bigsby medal by the Geological Society of London (1909).

The Walker prize of the Royal College of Surgeons, founded to encourage investigation into the pathology and therapeutics of cancer, has been awarded to Dr. E. F. Bashford, general superintendent and director of the laboratory of the Imperial Cancer Research Fund of London. The value of the prize is 100*l.* The Cartwright prize, consisting of the Cartwright medal and 70*l.*, has been awarded to Mr. H. P. Pickerill, professor of dentistry and director of the dental school at the University of Otago, New Zealand, for his essay on "The Prevention of Dental Caries." The Jacksonian prize has been awarded to Mr. K. Macfarlane Walker, of St. Bartholomew's Hospital, for his essay on "Tuberculous Disease of the Urinary Bladder and Male Genital Organs."

All the necessary arrangements have now been made by the General Post Office and the postal authorities abroad for a prolonged series of long-distance tests over the new submarine telephone cable which, as already stated in these columns, has been laid between Dover and Cap Grisnez. The tests will take place between various provincial towns in England and towns in Holland, Germany, and Switzerland, and it is expected that our foreign telephone service will be very greatly extended in consequence. No public service, however, will be offered until 90 per cent. of the test calls have proved successful. When this fact has been ascertained, there is no reason why, under ordinary conditions, speech over the line should not be quite distinct. There must, however, always be the chance that gales and blizzards may cause interruptions on the land lines, as these in most cases are still carried overhead.

On Wednesday, April 5, a very interesting exhibition was held at the Natural History Museum, South Kensington, when all the subscribers to the British Ornithologists' Union Expedition to Dutch New Guinea were invited to inspect the first collections of mammals and birds. The expedition is still attempting to reach the Snow Mountains, but it will be remembered that two members of the party, Mr. W. Goodfellow, the leader, and Mr. G. C. Shortridge, have been invalided home. The latter brought with him a large zoological collection, including about 1100 birds and 100 mammals. These have now been examined, and though procured at a comparatively low elevation (none having been obtained above 21,000 feet), the birds especially are of the greatest value and rarity. Quite a number were hitherto unrepresented in the national collection, while some five or six appear to be new to science. One of the most notable acquisitions is a magnificent bird of paradise (*Xanthomelus ardens*), which is yellow, with an orange-scarlet head and tippet. A small series of this fine bird was sent home, including adults of both sexes and a male in immature plumage. Among the novelties we may specially mention two brilliantly coloured parrots belonging to the genera Cyclopsittacus and Aprosmictus, likewise a beautiful fruit-pigeon of the genus Ptilopus. The collections were much admired, especially the many brilliantly coloured species to be found among the birds of paradise, parrots, kingfishers, rollers, pittas, &c. The mammals, though less showy, were also of great interest, while the drawings by Mr. Shortridge of bows and arrows, stone axes and clubs, paddles, &c., were much admired. The ethnological collection has not yet arrived, but is sure to prove of special interest.

It has been commonly taken for granted that a convenient and effectual way of encouraging scientific research is by the foundation and endowment of prizes for investigations dealing with specified subjects. The results published in the *Rendiconti* of the Lombardy Institution, xliv. (2), 1, recently received, seem to indicate that such endowments not infrequently fail to accomplish the desired object. The institution offered seven prizes for scientific subjects, one medal for industry, one for agriculture, a prize for commercial success, and others for economical, philosophical, literary, and forensic subjects. The industrial medal was awarded to one of three competitors, and for the Brambilla commercial prize eighteen firms competed, nine of which received awards and medals; but only two awards were made for work in science, and none in agriculture. These results are the more remarkable in view of the subjects on which dissertations were presented. The competitors for the agricultural medal seem to have introduced substantial improvements in cheese-making, based on a scientific study of bacteriology, but were apparently disqualified because their process had not met with such universal adoption that further recognition was unnecessary. The prize founded for the cure of pellagra seems to have been unawarded, in spite of researches of considerable scientific value having been made in connection with this disease. But the most remarkable fact is that a prize offered for improvements in dirigible balloons has now remained unawarded for three consecutive years. At a time when aërial navigation has made its greatest progress, it should surely have been possible to find many Italian aviators or aëronauts worthy of a prize founded long before the days of aviation.

An exceptionally long spell of easterly and northerly winds has prevailed over the whole of the British Islands, continuing for four weeks with the exception of a break or two lasting only for a few hours, and there have only been four days to April 11 at Greenwich since March 4 with the temperature in excess of the average. The day temperatures were low in March, but the nights were often fairly warm, with the result that the mean temperature for the month was in good agreement with the average. Since April set in, the cold has intensified, and the day temperatures have been remarkably low for the time of year. At Greenwich the maximum shade temperature on April 5 was 36·1°, and on April 6 38·0°. The observations at Greenwich since 1841 only show one day with the maximum temperature below 40°, a reading of 36·3° being recorded on April 19, 1849. The lowest minimum temperature at Greenwich during the recent cold spell was 26·7° on April 6; this is not remarkably low and has been occasionally equalled of recent years. The mean temperature for the week ending April 8 was 37·9°, and apparently the Greenwich observations only yield one period of seven days in April with so low a temperature since 1841, the mean for the week ending April 10, 1888, being 36·4°. The mean of the maximum or day readings for the week ending April 8 this year is 43·1°, whilst for the specially cold week ending April 10, 1888, it was 44·1°, so that the recent cold spell is the coldest on record for April so far as the maximum temperatures are concerned. The summary of the weather for the week ending April 8 this year, just issued by the Meteorological Office, shows that the mean temperature for the period was much below the average over the whole of the British Islands. The coldest district was the south-east of England, where the mean for the week was 36·9°, which is 8·3° below the average of the past twenty-five years. The deficit amounted to nearly 7° in the east and south-west of England and in the Channel Islands, and to 6·4° in the Midland counties. During the middle of the week the thermometer remained abnormally low over the eastern and southern counties of England, barely exceeding 32° at a few places, and at Tunbridge Wells on April 5 the highest temperature was 31°. The lowest minima, recorded on April 5 or 6, ranged from 17° in the east of Scotland and 20° in the west of Scotland, to 26° in the north-east and north-west of England. Snow was of frequent occurrence in nearly all parts of the kingdom.

In *Man* for April Mr. W. L. H. Duckworth describes a skull of the second Neolithic period found in a mound at Tsangli in Thessaly, and now deposited in the Cambridge Museum. In form it is mesaticephalic, and a deep incesura subincutalis reduces the height of the mandible in front. This last character is almost the only distinctive feature of the specimen. If, as may be inferred from its association with objects of undoubted antiquity, this specimen is of ancient date, it proves the existence of a highly evolved type of cranial form in Thessaly at this early period, modern examples indicating that the more usual form of skull in this part of Greece is longer and narrower than at the earlier period.

Mr. H. St. George Gray, in his report of the third season's work at the Maumbury Rings, records some additional discoveries. The remains now disinterred include two skeletons of the Romano-British period, with two of later date. We have as yet no certain knowledge of the age of the surrounding embankment, which cannot be fixed without further excavation. Socket-holes indicate the position of the railing erected for the protection of the spectators, and at the bottom of the arena some most interesting ceramic remains were unearthed, establishing the fact that the shafts date from the Neolithic period. The pottery consists of pieces of a rude vessel, black in

colour, with a dull red-brick tinge on the exterior only. It was imperfectly fired, and was composed of flint, quartz, and bone, but without any trace of chalk, calcite, or any form of limestone.

Among the pressing wants for the study of the evolution of human culture in these islands is the establishment of a folk-museum to contain the numerous archaic implements and utensils still to be found in the more secluded parts of the country, but which are now rapidly disappearing. The Pitt Rivers Museum at Oxford does something to fill this gap in our collections, and if its accommodation and resources could be increased, the work of forming and arranging such a collection could not be placed in better hands than those of its present curator, Mr. H. Balfour. Mr. J. Edge-Partington, in the April number of *Man*, illustrates the abundance of such material by describing, with drawings, a series of such primitive domestic implements and vessels collected from farmhouses in North Wales, where they are rapidly disappearing from use. Many of these are of a very primitive type, such as the collar used to control rams in the rutting season, curious spades and knives, a dish used for the dipping of rush lights, and a grooved rolling-pin for making oat cakes.

The Bio-Chemical Journal for March (vol. v., Nos. 8 and 9) contains a memorial notice of Dr. Christian A. Herter, of New York, who recently died at the early age of forty-five. His greatest work was his study of the complex elusive diseases set up by the development of an abnormal bacterial flora in the intestinal canal.

A chart containing the essential features required for the description and identification of bacterial species has been issued by a committee of the Society of American Bacteriologists, consisting of Messrs. Chester, Gorham, and Erwin Smith. The chart is a most comprehensive one, and includes a glossary of terms; it deserves the serious consideration of all bacteriologists.

No. 39 of the Scientific Memoirs of the Government of India is by Lieut.-Colonel Sutherland, and discusses in much detail the applicability to medico-legal practice in India of the biochemical tests for the origin of blood stains. As regards the precipitin test, the age of the blood stain, at least up to twenty-seven months, makes no difference in the applicability of the test.

The report of Dr. Bashford, the delegate of his Majesty's Government to the second International Conference on Cancer Research, held at Paris in October last, has recently been issued. Among other subjects he directs attention to a paper dealing with certain tumours occurring in the sugar-beet and allied plants. These tumours can be grafted on to other healthy plants, and no causative parasite can be detected in them. From their general biological behaviour it appears justifiable to assign to them in the vegetable kingdom a position analogous to that occupied by cancer in the animal kingdom.

The fatality of fractures of the leg and of lobar pneumonia as deduced from hospital mortality rates, 1751–1901, is the subject of a statistical study by Messrs. Greenwood, jun., and Candy (Journ. Roy. Statistical Soc., lxxiv., part iv., 1911). It seems that the fatality of lobar or ordinary pneumonia has changed little during the last fifty years, the fatality of compound fractures of the leg has steadily diminished down to the present time, and the fatality of simple fractures of the leg diminished greatly and steadily down to fifty years ago, but since then the change has not been regular. The curious point is brought out that cases of simple fracture in the old days were kept in hospital often for months, and sometimes for much longer, and the patients frequently developed bedsores and an unhealthy condition, which resulted in death.

In a recent short paper (*Parasitology*, vol. iii., No. 3, 1910), Dr. A. E. Shipley records five species of pentastomids from various Indian and African reptiles, including a new species of Porocephalus from the tortoise *Kachuga lineata*. The most interesting fact in the paper, however, is the occurrence in the pharynx of an Indian crocodile, captured on the mouth of the river Hooghly, of *Linguatula subtriquetra*, a parasite hitherto known only from the American *Caiman sclerops*.

No. 6 of the fourth volume of the Records of the Indian Museum is devoted to a revision, by Miss G. Ricardo, of the Oriental gad-flies of the genus Tabanus. No fewer than forty new species, including one from Celebes (which the author excludes from the Oriental region) and three from other regions, are described in the monograph; on the other hand, a large number of reputed species are relegated to synonyms.

The Rugby School Natural History Society, of which we have received the report for 1910, is to be congratulated on a marked increase in the number of its members, of which the total is now 425. The activity of the various sections has been, on the whole, well maintained, while some of them have exhibited remarkable energy and enthusiasm in their work. An interesting innovation in the present report is a record of the scientific work of old members of the society.

A contribution to our knowledge of the modern reptile fauna of Africa is made by Mr. F. Siebenrock in vol. cxix., part vii., of the *Sitzber. k. Akademie der Wissenschaften*, Vienna, who describes, with four plates, a large collection of chelonians made by Messrs. Pöck and Brunnthaler in the south and south-west. Eleven species—none new—are recorded, of which *Homopus boulengeri* and *Testudo bergeri* are figured. Special attention is directed to a series of *T. oculifera*, which is regarded as of importance in connection with the evolution of the colour-pattern. In the author's opinion, this species and *T. geometrica* constitute in this respect a subgroup phylogenetically distinct from the other members of the same group.

Scales of fishes brought home by Dr. F. Hatch from the Ecca Shales, near Ladysmith, of which an account is given by Dr. Smith Woodward in part ii. of the second volume of the Annals of the Natal Museum (pp. 229–31), are of interest as affording further evidence of the existence of an abundant fauna of Palæoniscidæ in southern Africa during early Mesozoic and late Palæozoic times. Scales of the same general type have been previously obtained from the Karu formation of the Cape and the Permo-Carboniferous of Rhodesia and Nyasaland. The last-named were referred by Dr. Traquair in the Quart. Journ. Geol. Soc. for 1910 to Colobodus, while the Rhodesian and the new Natal specimens represent the genus Acrolepis, of which there may be two species.

The Times of March 27 devotes an article to the wild fauna of South Africa in connection with the forthcoming display in the Zoological Society's Gardens in Regent's Park of a representative series of South African animals, to be called the King's collection. The collection, which already includes a large number of species, is to be presented to his Majesty in commemoration alike of his Coronation and of the establishment of the Union of South Africa. According to the latest information from the

Cape, the animals are being drafted to various ports previous to their shipment for this country. It is unfortunate that a southern seal recently received at the gardens, which is to be included in the African collection, is alluded to in the article as Ross's seal (*Ommatophoca rossi*) of the Antarctic, whereas it is really, as pointed out by Mr. Pocock in *The Field* of April 1, a young specimen of the sea-elephant or elephant seal (*Macrorhinus leoninus*). It was obtained from the Crozets, and is the first living example of its kind received in the gardens, and probably in Europe. The young animal is very like Ommatophoca, having a short, blunt muzzle and very large eyes.

IN an article published in *The Fortnightly Review* for April, Mr. F. G. Aflalo records his impressions of the London Zoological Gardens on paying his first visit after a three years' absence from England. His impressions are altogether satisfactory, and he especially commends the removal of the society's offices to the gardens, as the result of which the whole establishment is under the immediate eye and control of the secretary. It is added that, "as a result of this new control, we have the evidences of success on all sides, not merely in the condition and housing of the animals, but also in the higher birth-rate, lower death-rate, and increase in the number of both fellows and visitors to the gardens." Commendation is also accorded to the systematic plan on which the whole laying-out of the gardens is being remodelled, so far as existing buildings will permit, and the erection of new buildings and the construction of new enclosures with the view of a striking and picturesque general effect. Such changes must, however, of necessity be slow and gradual, as their cost is great. With its distinctly unfavourable conditions of climate and soil, the "New Zoo" cannot hope to rival in all respects similar establishments situated under sunnier skies, but, nevertheless, it "has overcome many obstacles, climatic and otherwise, and the result is something of a triumph."

THE annual report for 1909 issued by the director of the Sydney Botanic Gardens and Government Domains contains a few illustrations, one of which provides a view of the Centennial Park and another illustrates a clump of trees of *Casuarina glauca* in the botanic gardens. The cultivation of succulents is receiving special attention, and an extensive planting of palms in the domain is recorded. Among the noteworthy plants under cultivation mention is made of *Beilschmiedia Tarairi*, a New Zealand silver-leaved tree, analogous to the copper beech; an Australian natural hybrid, *Brachychiton populneo-acerifolius*; and two native plants, a white-flowered composite, *Olearia Flocktoni* and *Drymophila Moorei* (Liliaceæ). The publications emanating from the department include parts of the Forest Flora and several pamphlets on useful Australian plants.

PARTLY for the purpose of comparison with the working of the forests of *Pinus longifolia* in the North-west Provinces of India, a description of the State pine forests of Landes and Gironde in France is contributed to *The Indian Forester* (December, 1910). The area of sand dune converted into forest amounts to 200,000 acres, and, in addition, there is a littoral dune and protective wooded belt of one quarter of that area. The dunes are controlled by fascines and plantations of marram grass. *Pinus maritima* is grown as a pure crop for timber and resin under a rotation varying from sixty to seventy-five years. The species seeds freely from about an age of twelve years. Tapping for resin begins on trees about thirty-five years old, and proceeds until the tree is cut down. Details of tapping, the instruments used, and distillation are given.

IN plant hybrids raised by crossing *Œnothera biennis* and *Œ. muricata*, Prof. H. de Vries has observed some distinct features, which are indicated in a preliminary paper published in the *Biologisches Centralblatt* (February 15). In the first instance, the reciprocal hybrids *bm*, *mb*, are distinct from each other and from their parents, although clearly resembling the parent from which pollen was taken. The two resulting hybrids were then reciprocally crossed, $bm \times mb$, $mb \times bm$, when the former lost all traces of the species *muricata* and the latter all traces of *biennis*. The conclusions are formulated that for these two species the pollen cells bear special characters not shared by the egg cells, and that the characters of the grandfather cannot be transmitted through the mother nor those of the grandmother through the father. Similar results, *i.e.* dominance of the male parent and elimination of the characters of the female parent, were obtained when either of these species was crossed with allied species.

IT may not be generally known that the annual lists of "Geological Literature added to the Geological Society's Library" (Burlington House, London) can be purchased by the public. The issue for 1910 includes books and papers received up to December 31 in 1909, and the subject-index enables a reader to refer to the geological work of the whole year under almost any heading that may be in his mind. We see, for instance, that eighteen authors have written on Colorado, ten on laterites, and five on Natica. The list is especially important as an index to the geological journals of the world.

MR. P. MACNAIR has prepared an "Introduction to the Study of Rocks" as a guide to the rock-collections in Kelvingrove Museum, Glasgow (1911, price 3*d*.). It is well illustrated by photographs of rocks in the field, in hand-specimens, and in thin slices. The rock-forming minerals are also described, with figures of characteristic forms. Objection may be taken to the description of quartz and calcite as hexagonal, and to ilmenite as a "ferriferous titanite"; but the notices of the minerals and rocks are clear and adequate. Numerous drawings of sections of Scottish rocks are included in the text, and the book is distinctly attractive as an introduction to petrography.

FOR the benefit of teachers of geography in the State, a series of chapters dealing with the geography of Ohio State, by Mr. F. Carney, are appearing in the Bulletin of Denison University. Those treating of transport, glaciation, and the economic mineral products, provide useful summaries of information relating especially to Ohio.

PROF. HUNTINGTON, in the February number of the Bulletin of the American Geographical Society, describes the Karst country of southern Asia Minor, where to the south and west of Konia many of the streams end in dark, deep pools, in which the water sinks slowly underground. Much of the country, and especially the great plain of Axylon to the east of Konia, is too dry to be fruitful unless artificially supplied with water. Considerable work is being done whereby the waters of lake Bey Shehir (Kirili Göl) will be diverted, by means of a canal, from the lower lake of Kara Viren, where much is now lost, and will be carried through the Charsbembeh gorge to the plain below, where it is expected to put about 350 square miles under irrigation when the canal is opened by the end of 1912.

IN the *Revue générale des Sciences* for March 15, M. F. Diénert discusses the report of the commission which has

investigated the floods of the Seine valley in 1910, and made recommendations to mitigate the disastrous effects of future ones. The predictions of the Hydrometric Service were, on the whole, very correct, but the coincidence of flood waves in different tributaries, and the reduction of the effective channel by bridge piers, quays, and floating structures resulted in widespread inundation of the city. Three works were recommended by the commission, each of which would entail considerable outlay, but one at least, to take a branch from the river Marne by Claye to Epinay, would be of considerable economic value also. The other projects, to widen the left branch of the Seine and to deepen it between Suresnes and Bongival, will also receive a further study.

The meteorologist of the Commonwealth of Australia has published his annual rain map of Australia for the year 1910, in which he shows that the coast lands in the south-west, almost the whole of the State of South Australia, or the States of South Australia and Queensland, northern New South Wales, and eastern Victoria received a rainfall above the average in 1910. This was especially so in the northern territory of South Australia, where the heavy fall was due to the activity of the monsoon rain influences. The difference between the actual fall in 1910 and the normal in some cases is very striking, showing frequently an increase of 50 per cent. The lowest rainfall, under 5 inches, was in central Western Australia. The highest, about 180 inches, was on the coast of Queensland half-way between Cook Town and Townsville. The district near Zeehan (Tas.) received above 100 inches.

"The Supposed Cold of Winter Anticyclones" is the title of a useful note by Mr. W. H. Dines in *Symons's Meteorological Magazine* for March. In an interesting summary of the weather of January, in the magazine of the previous month, reference was made to the striking exception to the old dogma that high barometric pressure in winter is almost invariably associated with persistent frost. Mr. Dines, who some years ago assailed that idea in the Quarterly Journal of the Royal Meteorological Society, now points out, *inter alia*, that during the 50 years 1841–90, the Greenwich records show 74 periods of frost. Out of these, 20 (with 216 days of frost) occurred with the mean of the barometer below 29·80 inches, and 13 (giving 93 days) with a mean above 30·20 inches. Every frost noted for severity or length had occurred in the low-pressure series. Also at Christiania, Berlin, and Geneva no connection between the monthly winter means of the height of the barometer and of the temperature is shown. The statement in question is still made in some text-books, and may possibly be true in drier countries, *e.g.* in Asia and North America. Kite and balloon observations have shown that the air a few thousand feet high during an anticyclone is unduly warm.

The climatology of 1910 is discussed in the usual annual summary which MM. Flammarion and Loisel contribute to the February number of *L'Astronomie*. The discussion is based on the daily observations made at the Juvisy Observatory, and the different results, in addition to being plotted all on one chart, are compared with the analogous monthly, seasonal, and yearly results registered during the past twenty-five years. The year 1910 was almost entirely a bad one from the weather point of view. An abnormally low barometer, which beat the minimum record for December, was accompanied by excessive humidity and rainfall, the number of rainy days (212) exceeding that of any year since 1893, while the amount of rain was 818·4 mm., or 275·9 mm. above the annual mean; its partition among the seasons was also abnormal. Although the mean temperature was the highest since 1906, the spring and summer were deficient in sunshine, there being 1555 hours spread over the 301 days on which sunshine was recorded; in 1909, 1970 hours were recorded for 300 days. In consequence of this state of sunless, cold humidity, the vine, wheat, and other crops met with disaster, and, as a "comet" year, 1910 compared very unfavourably with the legendary years 1811 and 1858.

An abstract of the first three of the lectures on "Radiant Energy and Matter," which Sir J. J. Thomson is delivering at the Royal Institution, will be found in *The Electrician* for March 24. The first lecture dealt with the measurement of radiant energy and the laws which have been found to connect the energy radiated with the temperature of the radiating body. The second dealt with the pressure which radiation exerts on the body on which it falls, and the applications of the results of experimental and theoretical work on this subject to cosmical problems. The third dealt with the visible radiations, their production by fire-flies and by illuminating engineers, and their perception by the human eye.

In the March number of *Terrestrial Magnetism and Atmospheric Electricity*, Mr. J. A. Fleming, of the department of terrestrial magnetism of the Carnegie Institution, describes two new types of magnetometer which have been constructed for land observations in districts more or less difficult of access. The first is a theodolite magnetometer for astronomical work and the determination of declination and horizontal force, the second is a universal instrument for astronomical work, declination, horizontal force, dip, and by Lloyd's method total intensity. In both cases the magnet system consists of a long and a short magnet each embedded in a brass cylinder of a standard size. The suspension is of phosphor bronze strip. The first instrument is built on the usual lines, but the reduction of size has necessitated changes of details. The second departs considerably from the traditional form owing to the combination of a dip circle with the deflection magnetometer. The two instruments, packed in their cases, weigh 11 and 13 kilograms respectively, and the degree of accuracy obtained by means of them is about the same as that secured with the older and much heavier instruments.

Messrs. Adam Hilger, Ltd., have sent us a copy of their new general catalogue, which should be in the hands of every worker in the ever-widening field of spectroscopic research. Not only are a large number of spectrographs figured and described, their special features and adaptability for various purposes are carefully explained, so that the book is something more than a mere catalogue. One of the many features to which the firm pay special attention is the quartz-spectrograph, with which we know excellent results have been obtained. These are now made in a large variety of forms, some of which are easily convertible, so that their action can be modified to suit the special end in view. An ultra-violet stellar spectrograph, giving a spectrum 50 mm. in length from λ 3000 to λ 8000, is quoted at 53*l*., and with its large angular aperture should prove a very effective instrument. A wedge spectrograph for technical use, designed by Dr. Mees for the rapid and permanent recording of absorption, transmission, and sensitivity curves, is sold, with the necessary accessories, at 17*l*. The catalogue also contains figures and descriptions of many accessories—gratings, slits, tubes, &c.—and of several special pieces of apparatus, such as

the echelon, the Fabry and Perot interferometer, &c. Those workers wishing to learn more of the latest forms of these special apparatuses should get section B of the catalogue, issued separately, in which, in addition to the descriptions, figures, and prices, complete bibliographies concerning them are given.

We have received the new edition of the "Descriptive List of Photographic Dry Plates, Filters, and Safelight Screens" manufactured by Messrs. Wratten and Wainwright, Ltd. (Croydon). The firm have recently installed apparatus for the critical examination of the effect of colour screens upon definition, a matter too often left to chance. With regard to the plates, &c., prepared specially for all kinds of scientific work, we notice specific statements as to those best adapted for photographing various parts of the spectrum, and the "high resolution plates," for which a "limiting separation of about 1/150th mm." is claimed, as against a separating power equal to about 1/40th mm. for ordinary plates. These special plates are slow panchromatic plates.

OUR ASTRONOMICAL COLUMN.

Detonating Meteor in Messina.—On Monday evening, April 10, at 7 p.m., people at Messina noticed a brilliant illumination of the sky, succeeded in about three minutes by four loud explosions like artillery discharges. The idea was that one of the ammunition magazines in a fort had exploded, but telegraphic despatches from Palermo, Catania, and Reggio di Calabria announce that a similar phenomenon had been remarked there, and that it had its derivation from a large bolide or some other meteoric disturbance. The interval of three minutes between the flash and sounds show that the disruption of the fireball occurred at a distance of about forty miles from the observer at Messina. More information is awaited. At other stations the object may have approached much nearer, if it did not, indeed, shower some of its disintegrated fragments to the ground. April 10 is a rather special date for large fireballs; it has furnished many fine specimens in past years.

Halley's Comet.—Writing to the *Astronomische Nachrichten* (No. 4489), M. Antoniadi shows that whilst Prof. Eginitis recorded the tail of Halley's comet as being directed towards the sun at 6h. 40m. (G.M.T.) on May 20, 1910, five observers who saw it at various short intervals before that time, and five who saw it after, recorded the tail as directed from the sun; only twenty-nine minutes separated the times of observation at Sonnwendstein and Athens, the former being 7h. 9m. (G.M.T.). Mr. Evershed, observing at Kodaikánal about 2h. (G.M.T.) on May 20, saw no trace of a tail directed towards the sun, although he looked specially for it.

The same number of the *Astronomische Nachrichten* contains a long series of observations of the comet made at Besançon (December 10, 1909, to June 29, 1910) and at Berlin (December 16 to June 10); M. Chofardet reproduces a drawing showing the magnificent fan which preceded the sharp nucleus on May 27.

Circulation in the Solar Atmosphere.—From an examination of 3323 prominences shown on photographs taken between January, 1904, and December, 1910, with the Rumford spectroheliograph at the Yerkes Observatory, Dr. Slocum has derived some valuable data concerning the circulatory currents in the solar chromosphere; the light of the H calcium line was always employed. Of the total examined, 1094 prominences, either by their shapes or movements, indicate a horizontal current, and as the average height to which these extended was 0·7′, or 30,000 km., the results represent the average poleward components of the solar atmospheric circulation from the lower surface of the chromosphere up to that height. Dr. Slocum finds that in middle latitudes there is a tendency for movement towards the poles, and in high latitudes a tendency towards the equator; near the equator the motion is practically negligible. The contrast between the two tendencies is greater in the northern hemisphere in the ratio of at least 2 : 1.

Among the earlier plates there were few which afforded data from which the velocities of the motions could be determined, but during the past year suitable plates for this purpose have been taken regularly. There is some difficulty in determining which of the observed movements may be ascribed to systematic circulation and which to local explosive outbursts, but ten selected cases give velocities of from 0·5 km. to 10 km. per second for the component of the circulatory movement which is perpendicular to the line of sight; one detached cloud, floating at an elevation of 442″, or 320,000 km., showed a velocity of 50 km. per second. Dr. Slocum points out that these results are not necessarily a contradiction to those obtained by Dr. St. John, who failed to detect any currents of appreciable velocity parallel to the solar surface; the two researches deal with different levels in the solar atmosphere. He further suggests that as his results depict the movements at an average height of 30,000 km., they probably apply to an upper current analogous to terrestrial anti-trades; a later discussion to deal with the different levels is promised (*Astrophysical Journal*, vol. xxxiii., No. 2, p. 108).

The Popularisation of Astronomy.—From *The Yorkshire Weekly Post* for April 8 we learn that the excellent idea of out-of-door astronomical talks has also been suggested by Mr. J. H. Elgie as a useful item in the programme of the Leeds Astronomical Society. For the past three weeks the society has been waiting, in vain, for a favourable sky so that they might hold the proposed Saturday evening meeting. Such meetings, open to the public, might easily be organised, and would probably do a great deal to dissipate the lamentable ignorance concerning the stars which is so frequently displayed by the general public.

The Antwerp Astronomical Society.—Among the many interesting matters recorded in the sixth annual report (1910) of the Antwerp Astronomical Society, it is of interest to learn that the society's observatory is being very generally used by a large number of students in the local schools, who, under the guidance of their tutors, visit the observatory and have the equipment, &c., explained to them. A new communal observatory is to be placed on the top of a school which is in course of erection in the city. An analysis of the observing weather during 1910, made by M. Felix de Roy, is also of interest. Of the 365 days in 1910, observations of the sun were possible on 269 days, and night observations were possible on 142; for 1909 the figures were 292 and 151; in 1908 there were 156 good nights; in 1907, 145; and in 1906, 102.

Spectroscopic Binaries.—The Journal of the Royal Astronomical Society (Canada, vol. iv., No. 6) contains the orbits of the spectroscopic binaries 93 Leonis and ϵ Ursæ Minoris as determined by Messrs. J. B. Cannon and J. S. Plaskett, respectively, from plates taken at the Dominion Observatory, Ottawa.

Mr. Cannon made two determinations, using micrometer measures in the first and the comparator in the second, and, judging from the probable errors of an average plate, there is but little difference between the two methods; fainter spectra may be measured with the micrometer than in the comparator, but with poor lines for measurement the latter instrument probably affords a better agreement among the measures. The period of 93 Leonis is found to be 71·7 days, and the eccentricity of the orbit is very small.

For ϵ Ursæ Minoris Mr. Plaskett finds a period of 39·482 days, a range of velocities of 63 km. per sec., and a small eccentricity; the velocity of the system is −11·398 km. per sec.

EXPERIMENTS WITH COAL DUST IN FRENCH COLLIERIES.

Soon after the dangers due to the presence of coal dust began to be realised in this country, and, as a consequence, regulations regarding the composition and methods of employing explosives in dusty mines had been added to the Statute-book, the number of great explosions occurring within a given time underwent such a remarkable diminution that for several years it seemed almost as if they were about to cease altogether. But a partial

recrudescence having set in later, it became apparent to those who were watching the course of events that complete immunity could not be attained until measures were adopted for dealing with the coal dust in the haulage roads, as well as at the points at which blasting shots were about to be fired. It was equally apparent that no far-reaching legislative action such as this could be taken unless the mining community, which had hitherto regarded the dangers of coal dust as more or less hypothetical, could be convinced of their reality, by ocular demonstration on a large and imposing scale. Accordingly, when called upon to give evidence before the Royal Commission on Mines some years ago, the present writer and others recommended the construction at Government expense, at an estimated cost of 10,000*l*., of a large apparatus to be used for this purpose. It is, perhaps, needless to remark that the Treasury declined to find the money, just as they had, some twenty-nine years ago, declined to find 5000*l*. for the construction of a similar gallery, 500 feet long by 6 feet in diameter, intended to be used for the same educative purpose, when asked to do so by the Royal Commission on Accidents in Mines, for one of the members of which (Sir W. Thomas Lewis) the present writer had obtained tenders.

The suicidal blindness of this kind of policy from a national point of view must surely be becoming apparent. It was at this juncture that the Mining Association of Great Britain stepped in and erected the experimental gallery at Altofts Colliery, which has been already described in a previous review (Nature, February 9, vol. lxxxv., p. 487).

When it was recognised in France that the explosion at Courrières Collieries, which claimed more than 1100 victims in 1906, was due to coal dust alone, the opposition which the Commission du Grisou had, up to that time, maintained against the coal-dust theory was effectually crushed, and it became necessary for those responsible for the safety of French mines either to accept the data regarding the behaviour of, and means of dealing with, coal dust already accumulated in other countries, or to accumulate quasi-original data of their own. The opportunity of adopting the latter alternative presented itself when the Comité Central des Houillères de France agreed to find a capital sum of 14,000*l*. wherewith to provide experimental appliances, and an annual income of 3000*l*. a year for current expenses as long as the experiments are continued.

The appliances which have been set up at Liévin Collieries in France are similar to, and intended to serve the same purposes as, those at Altofts and other experimental stations.

The experiments are being conducted by M. Taffanel, a member of the Corps des Mines, who has issued consecutively a number of very clear and able reports, describing the appliances, the methods of using them, and the results obtained with them.

In attempting, in his first report, to justify the attitude of antagonism to the coal-dust theory which his colleagues had just abandoned, he essays to throw a dart at the work of the present writer, but the weapon, having the form of a boomerang, naturally descends upon the unhappy heads of those he is trying to protect. It could not well be otherwise, for his subsequent voluminous descriptions of the mode of occurrence of a coal-dust explosion, the functions of the condensed and expanded waves and the position of the flame in the former, the influence of the weight of dust in a given volume of air, its fineness, the proportion of volatile matter contained in it, and the presence of more or less inert matter and moisture, had all been anticipated in the work in question; so that his own contributions to the subject, when divested of a vast amount of prolixity and a great array of numerical data, much of which is of doubtful, and most of only hypothetical value, largely partake of the nature of plagiarism.

Numerical data obtained by means of experiments of this kind are of no practical value except in so far as they can assist us in devising means for putting an end to great explosions. Thus, as it is known that the flame of an explosion in a mine can ascend to the top of a damp or wet shaft 900 or 1000 feet deep, it is not of the least importance to know whether an explosion in an experimental gallery can or cannot leap across a dustless zone a few hundred feet in width, and raise and ignite coal dust lying at its farther side. It is equally unimportant to know with what velocity the flame travels in, or what particular pressure is exerted by, an explosion of dust of greater or less fineness, or containing more or less volatile matter, since we are absolutely powerless to regulate any one of these conditions in a dusty mine, and know that an explosion, once begun in it, will spread as far as there is coal dust to maintain it.

In further attempting to cover the retreat of his comrades, M. Taffanel pleads that they had no previous experience of coal-dust explosions in France before the one at Courrières Collieries. But the present writer has a lively recollection of reading the accounts of two great explosions at the Jabin pits in France, which occurred one after the other within a short period of time, some thirty or more years ago, and of making a mental note at the time that, judging by the phenomena as described, they were both due to coal dust and not to firedamp, as was then announced. Again, surely M. Taffanel does not now seriously contend that the four great explosions, Chatelus, 1887, Verpilleux, 1889, Pelissier, 1890, and Manufacture, 1891, were attributable to any other agent than coal dust.

We frankly agree with M. Taffanel that his countrymen are, as a rule, in the van of progress; that although they did not originate the method of measuring the proportion of firedamp in the air by means of the firedamp cap (*for this see* Proc. Roy. Soc., vol. xxiv., pp. 361 to 367), they have produced an excellent lamp for the purpose; and that their appliances and regulations for dealing with firedamp, and for blasting, are amongst the most perfect in existence, and we heartily congratulate him and them upon the results of these measures. But *qui s'excuse s'accuse*: and the mere fact that they have been able to perfect their methods of dealing with firedamp makes it all the more regrettable that they so resolutely refused to believe in the dangers of coal dust, since it is practically certain that had they lent their powerful aid to the solution of that question from the beginning, it would have been settled long ago, and at least two Royal Commissions which examined the subject successively in this country would have been saved the ignominy of making halting and half-hearted suggestions for grappling with it.

The first series of M. Taffanel's experiments was made with an auxiliary apparatus consisting of two pieces of sheet-iron pipe, each 25 feet long by 2 feet in diameter, placed side by side and connected to each other at each end by short pipes of the same diameter. The air was made to circulate through this system by means of a fan working at the middle point of one of the longer pipes with sufficient rapidity to keep fine dust suspended in it, and shots were fired from a cannon into the dust-laden air from one end or the other of the second long pipe. By this means it was ascertained that dust containing 11·3 per cent. of volatile matter (ash and moisture deducted) could not be ignited by the explosion of a half cartridge of gelatine dynamite fired electrically from the cannon without tamping, but that dust containing 15·4 per cent. and up to 53·2 per cent. could be invariably ignited when the air contained a minimum weight of 138 grammes per cubic metre of that with 15·4 per cent. and 40 grammes per cubic metre of that with 53·2 per cent., and similarly an intermediate weight for all intermediate proportion of volatile matter.

The second series of experiments was made with the same apparatus (the shots being fired in the direction of the air current), one set to ascertain the effect of varying the weight of the explosive, the other to determine the effect of mixing the coal dust with slate dust. The coal dust employed was prepared with Liévin coal containing 29 to 30 per cent. of volatile matter and 3 to 5 per cent. of ash, and of such a degree of fineness that only 5 per cent of it was unable to pass through the sieve with 5625 meshes per square centimetre.

By these experiments it was ascertained, first, that a certain minimum weight of explosive was sufficient to produce ignition, and that increasing that weight made little or no difference in the length of the resulting coal-dust flame; and, secondly, that the addition of slate dust to the coal dust reduced the velocity of propagation of the flame, although inflammable clouds were obtained with as much as 62 per cent. of slate dust, and it seemed doubtful whether under certain conditions propagation would not take place with as much as 78 per cent.

These results are to some extent in keeping with those btained by the present writer on June 5, 1896, when he nade the first experiments of this kind with mixtures of ombustible (in that case lycopodium) dust and inert dusts chloride of calcium, dry clay, common salt) at University College, Cardiff, in the presence of Mr. Robson, then Chief nspector of Mines for the South Wales district, and Mr. 'aughan Nash.

The third series of experiments was made with the rincipal gallery, which in 1908 was 71 yards long, in 1909 vas lengthened to 250 yards, and in 1910 to 328 yards. The first 33 yards of its length is constructed with ferro-oncrete specially strengthened with steel joists. Its form s trapezoidal in cross-section, and its internal dimensions re 6 feet high, 4 feet 7 inches wide at the top, and feet 3 inches wide at the bottom. This shape and these limensions were chosen with the object of assimilating its nterior to that of a roadway in a mine, and the similarity s still further accentuated by means of props and caps set p at the usual distances apart in its interior. In its final orm, so far as one can gather from the descriptions, the emainder of the gallery is constituted by a sheet-iron ylinder, 6 feet in diameter, with one of its ends abutting gainst one end of the ferro-concrete section and its other nd open.

Two massive stone walls, one on each side of the free nd of the ferro-concrete part of the gallery, extend back-vards from the latter to a distance of 10 or 12 feet, and onstitute supports to a vertical barrier of strong wooden eams, with which that end is closed. The cannon from vhich charges of explosive are fired for the purpose of gniting mixtures of firedamp and air, or of raising and gniting coal dust in the interior of the gallery, can be fired orizontally at any desired height in the vertical centre-ine of the latter, with its muzzle extending through a ole in, and flush with the inner face of, the wooden arrier. Its bore is 2 inches in diameter and 23½ inches eep, and, except where specially mentioned to be otherwise, ts axis was placed at a height of 2 feet above the floor. The explosive employed was gelatine dynamite fired without amping by means of an electric fuse, and the minimum veight of charge that assured propagation of the coal-dust lame under ordinary conditions was 160 grammes.

A branch gallery built of masonry, connected at right ngles to the main gallery at a distance of about 17 feet rom its closed end, serves the purpose of a channel, through vhich air can be blown, by means of a ventilating fan, into nd through that gallery, and also affords a means of ngress to and egress from it.

When an explosion is about to be produced, the connec-ion between the main and branch galleries is cut off by losing a strong door at their point of junction.

There are twelve plate-glass windows about the middle eight of the ferro-concrete part of the gallery, through which the progress of flame in its interior can be seen from distance. Its cylindrical prolongation, on the other hand, embedded in the centre of a mass of debris, like a rail-ay embankment, about 6 feet high by 12 feet wide at the p, and with sloping sides.

The coal dust employed in the experiments is obtained by rinding coal as it comes from the mine, first in a ball-ill, and secondly in an Alsing pulveriser. The degree of neness attained in the latter depends upon the length of me during which the grinding is continued.

After having been first granulated in the ball-mill and en ground in the Alsing pulveriser for the length of time amed below, the following proportions of Liévin coal are rrested by a sieve of brass wire with 5625 meshes per quare centimetre,[1] viz. :—

Time	Per cent remaining on seive
0 minute	72·5
15 ,,	35·0
30 ,,	12·5
45 ,,	3·5
60 ,,	1·5

Some analyses of the same coal employed in the experi-ents are as follows :—

	Per cent.	Per cent.	Per cent.
Volatile matter (including moisture) ...	28·00	25·07	29·50
Ash ...	8·57	12·16	5·97
Volatile matter (exclusive of ash ...	30·60	29·30	31·40

The weighed quantity of dust employed in each experiment was scattered uniformly over the floor of the gallery by hand; that remaining unconsumed after the experiment was partly swept, partly blown out, by means of a strong current of air from the fan; and when it was desired specially to cleanse the gallery, jets of compressed air were employed for the purpose.

When it was desired to effect the ignition of the dust by means of an explosion of firedamp and air, part of the gallery next the wooden barrier was isolated by means of a paper diaphragm in exactly the same way as was first done for the same purpose in the Royal Society gallery of 1880–1, and afterwards in the Prussian gallery of 1884, and the gas and air already mixed was introduced into it in exactly the same way as an accurately measured quantity of firedamp was introduced into the isolated part of the Royal Society gallery, in which it was mixed with the air by being drawn into the centre and expelled from the periphery, of a rapidly revolving fan in the interior of the gallery itself.

The apparatus employed for measuring pressures is of the "crusher type," such as is employed in testing explosives. It consists of a cylinder, containing a hollow piston with a block of lead in its interior, and a small steel ball interposed between the block of lead and a fixed support. The pressure acts on the piston which presses the lead against the steel ball, and the latter, being prevented from moving by the fixed support, penetrates the lead to a greater or less depth. In spite of the extreme accuracy with which it is professed that the depressions produced in the lead block can be measured, a more clumsy and probably inaccurate method of measuring the comparatively small pressures here requiring to be dealt with could hardly well be imagined.

The appliance for measuring velocity, which consists of a counter marking fifths of a second, started at the moment the explosion commences and stopped by an observer when the flame appears at the end of the gallery, the length of which for this series of experiments appears to have been 65 metres only, seems to be hardly less trustworthy than the pressure recorder.

On the other hand, the flasks for collecting samples of the products of combustion immediately after the passage of the flame, from which the air had been extracted beforehand, and into which nothing could enter until a sealed glass tube which communicated with their interior had been broken by a detonator ignited by the flame of the explosion, seem to be satisfactory.

The firedamp employed in some of the experiments was obtained from the pit near at hand, stored in a gasometer, and mixed with air in the proportion of 9 or 10 per cent. before being introduced into the isolated part of the gallery in the manner already indicated.

Of all the explosives tested, dynamite was found to produce coal-dust explosions with the greatest facility. It was found that the explosion of 8 cubic metres (282½ cubic feet) of a mixture of firedamp and air, when ignited by means of 100 grammes of black powder, easily gave rise to a coal-dust explosion under favourable conditions; but that under less favourable conditions the superposition of a firedamp explosion upon that of dynamite actually diminished the chances of propagation. M. Taffanel's attempt to explain this phenomenon, by supposing that the large quantities of carbon dioxide and water vapour projected into the dusty atmosphere in consequence of the combustion of the firedamp are responsible for this result, is altogether erroneous. The true explanation is that the expanded wave, following after the condensed wave in the *cul-de-sac* constituted by the little gallery, overtakes and extinguishes the flame. The present writer observed the same phenomenon in his smaller Royal Society gallery of 1877–8, and succeeded in destroying the expanded wave and securing free propagation of the coal-dust explosion on every occasion by providing a flap-valve, opening inwards only, at the closed end of the gallery, through which air was drawn with sudden violence an instant after the firedamp mixture had exploded; and he has no doubt that M. Taffanel would have exactly

[1] Comite Central des Houillères de France Station d'Essais de Liévin-oisième Serie d'Essais, p. 9 (1910).

the same experience if he provided either a similar valve or a reservoir of air of sufficient capacity near the closed end of the *cul-de-sac* (such as exists in the form of branch workings in most mines), from which air could expand and thus wholly or partially destroy the vacuum. If he arranged his experiment in this way, he would have no difficulty in securing propagation by means of a firedamp explosion ignited by a spark, much less by 100 grammes of dynamite.

Many other points of importance might be referred to with advantage, but space would fail us were we to attempt to go further in this place, and the final remark we would make in regard to this series of experiments is that the water employed in damping the dust, which forms globules on the surface of the latter, does not appear to have been applied in the form of an exceedingly fine spray, repeated several times, in succession, with a short interval between each application, and we venture to think that if this had been done the results would have been different from those actually experienced.

The fourth series of experiments was made with the gallery lengthened to 230 metres (251½ yards), although the whole length was not always employed. For the first 32½ yards the form of the gallery was trapezoidal, with a lining of cement, the remainder cylindrical, with a lining of wood and with a floor. The coal dust was prepared from Liévin coal, with 29 to 31 per cent. of volatile matter and 6 to 12 per cent. of ash. The slate dust employed in some of the experiments was obtained from the pit. It contained 9 per cent. of volatile matter and 87 per cent. of ash, and was mixed with marly chalk, clay, siliceous sand, and boiler-furnace cinders. Mixtures of coal dust and inert dust were prepared by grinding them together. The mixture was simply spread uniformly on the floor and not stirred up mechanically before the explosion. The charge employed in creating the explosions consisted of 240 grammes of gelatine dynamite untamped and fired electrically, the axis of the cannon being 15¾ inches above the floor.

Fine dust was spread to a distance of 16½ feet in front of the cannon to insure ignition, but beyond that point coarser dusts ground for a quarter or half hour and even grains were employed.

Some explosions effected with half-hour dust were very violent, traversing the whole length of the gallery in 1⅓ seconds, with increasing velocity, which exceeded 1100 yards per second at the orifice, while the pressure, which was 28½ lb. per square inch for most of the distance, increased to between 42½ lb. to 71 lb. per square inch at 45 metres from the orifice, and to 156½ lb. per square inch at 11 yards from the orifice. With 900 grammes per cubic metre of quarter-hour dust, the flame traversed the gallery in 1·23 seconds, and the pressure attained 224 lb. per square inch at 10 metres from the orifice.

With a deposit of coal dust containing up to 33 per cent. of slate dust the coal dust was exploded, and the explosion was capable of becoming violent.

Passing over the experiments with dustless, watered and shale dust zones, and those made with obstacles of various heights, placed on the floor and on shelves at the sides of the gallery, we come to what are the most novel, and perhaps also the most interesting, of all the experiments, namely, the efficient results obtained in the way of arresting even violent explosions by placing loose, easily displaced cinders, or, *mutatis mutandis*, half-round sheet-iron tanks 40 inches long by 8 inches in diameter, filled with water on transverse planks one metre apart just under the roof of the gallery. It is to be hoped that these two methods of arresting explosions will be the object of further successful experiments, and it is not improbable that, after all, we may owe to France a debt of gratitude for pointing out a simple and efficacious means of effecting the object which all of us are so anxious to attain. May the present writer suggest in conclusion that possibly appliances of the nature of extincteurs or fire extinguishers, put into operation by the blast which precedes the flame of an explosion acting upon a movable vane which would open the passage for the escape of their contents, might be used instead of open troughs filled with water? The former would possess the indubitable advantage that they would retain their efficiency intact for any length of time; whereas the latter would require constant attention in the way of cleaning and refilling them. W. Galloway.

THE INSTITUTION OF NAVAL ARCHITECTS.

The spring meetings of the Institution of Naval Architects opened on Wednesday, April 5, at the rooms of the Royal Society of Arts. Owing to the death of Earl Cawdor, president of the institution, the chair was taken by Sir W. H. White, who announced that the council recommended the election of the Marquis of Bristol as president. The grant of a Royal Charter of Incorporation has received the Royal assent. The celebration of the jubilee of the institution, postponed from last year, will take the form of an International Congress on Naval Architecture and Marine Engineering, opening on July 4.

Fourteen papers were read and discussed. The problem of size in battleships was dealt with by Prof. J. J. Welch. Among other points raised in this paper is the contention that large dimensions expose a greater target to attack, a contention which must now be expanded to include the additional menace of missiles from dirigibles or aëroplanes. Assuming the attack to be delivered from a height of one mile, and therefore reasonably out of range of high-angle fire, a hollow bomb carrying 100lb. of explosive would take about twenty seconds to reach the water level, and would then have a striking velocity of about 500 feet per second. In twenty seconds a ship would change position some 540 feet, supposing her to be proceeding at 16 knots, and the probabilities of such a vessel being struck from above would be decreased if, at the moment of discharge of airship weapon, her helm were put hard over. The time, however, would not suffice to allow the vessel to sweep clear of her previous track before the missile reached water level, although the exposed area of deck in that track would be very much smaller than before. The difficulties associated with correctly judging speeds of battleships from the height named, and making proper allowance for cross wind currents, &c., combine to render a hit very uncertain if a single missile only is employed. It is stated, however, that arrangements are being made for dropping a number of such missiles from a single dirigible, in which case this form of attack would become a serious menace. It seems reasonable to suppose that the best protection from such attacks will be found in the counter-attacks by the same type of air-ship, associated with high-angle gun fire from the vessel attacked.

The Hon. C. A. Parsons and Mr. R. J. Walker gave the results of twelve months' experience with the geared turbines fitted to the cargo steamer *Vespasian*. In this vessel, the reduction of speed ratio of 20 to 1 is obtained by means of a spur wheel and pinion having double helical teeth. The vessel has now steamed 20,000 miles, and inspection shows that the wear in the teeth so far seems to be a negligible quantity. With the view of experimenting with different qualities of steel, a pinion of chrome nickel steel of tensile strength 55 tons per square inch, elastic limit 38 tons, and an elongation of 20 per cent. in a length of two inches, was tried and removed after two voyages. The corners of some of the teeth were found to be fractured, probably owing to irregular machining and to the material being too brittle. The original pinions were of mild chrome nickel steel of tensile strength 37 to 38 tons per square inch, and an elastic limit of 32 tons per square inch. These were replaced and have now carried the vessel more than 18,000 miles. A very noticeable feature has been the absence of racing of the engines under conditions when the propeller has been entirely out of the water. It is very difficult to observe any acceleration in the speed of the engines without the aid of a sensitive tachometer. This is owing to the very great angular momentum of the turbine.

Mr. G. S. Baker contributed a fully illustrated description of the National Experimental Tank and its equipment, including the model-making apparatus.

The whole of Thursday morning was taken up by a paper on Diesel engines for sea-going vessels, by Mr. J. T. Milton, of Lloyd's Register, a paper which provoked a very interesting discussion. Inducement to forsake the steam engine for ordinary sea-going vessels will be mainly the question of fuel economy. Even this important point would not of itself warrant a change to a new type of engine unless equal certainty of continuous efficiency on the voyages to be undertaken was provided, that is, as little risk of accident to machinery and as great facility for using temporary expedients for reaching port in case of break-

down of part of the machinery. There must also be a prospect of a reasonable cost of upkeep. Leaving warships out of account, oil fuel is only used on shipboard in those cases where the natural advantages render its use more economical than coal, and by vessels which trade regularly to ports where supplies can be obtained. For the ordinary cargo steamer which has to seek employment all over the globe, coal is still the necessary fuel.

The Diesel engine for marine purposes is made in three forms, viz., as a four-stroke cycle single-acting engine, a two-stroke cycle single-acting engine, and a two-stroke cycle double-acting engine. An auxiliary air compressor capable of producing a pressure of about 700lb. per square inch is required. The author has examined the turning moment diagrams of different arrangements of cylinders, and shows that a four-stroke cycle engine with twelve cylinders, a two-stroke with six cylinders, and a double-acting with three cylinders give fairly uniform Forsion moments, the ratio of maximum to mean being not greater than 1·15. With these numbers of cylinders there is nothing further to be desired regarding steadiness of motion. The Diesel marine engine should be Diesel only as regards the cylinders and their accessories, and should be of the ordinary marine type as regards all the rest of the engine. The question of the auxiliary machinery required is fully discussed in the paper.

Dr. Diesel stated in the discussion that any kind of oil may now be used in these engines, and that the use of the two-stroke cycle may be assumed in future for marine purposes. Some 250 vessels are now fitted or to be fitted with Diesel engines, a large number of these being submarines. The use of Diesel engines in submarines has so extended their radius of action as no longer to limit their use for coast defence merely. About 1000 horse-power is the largest power obtained from one cylinder up to the present, the cylinder being of the two-stroke double-acting type. Some makers are prepared to give higher powers from one cylinder.

Messrs. Richardson, Westgarth and Co., of Middlesbrough, are now constructing a set of single-screw Diesel engines of 1000 horse-power for a 3200-ton ship to the order of Lord Furness. These will be of slow-running type. The Anglo-Saxon Petroleum Co. have on order a single-screw vessel of 4250 tons to be fitted with 1100 horse-power Diesel engines, to be built by an Amsterdam firm.

Considerations affecting local strength calculations form the subject of a paper by Mr. J. Montgomerie. It is a truism that there is no such thing in the calculations dealing with the strength of ships as an actual quantitative stress in tons per square inch. "To design a ship from first principles" is a phrase which is often used in a sense implying far too much. All calculations of the strength of ships are comparative. Structural arrangements of vessels which have stood the test of experience are taken, and are compared and contrasted with those proposed in any given case, or a corresponding arrangement is derived from them which shall be satisfactory in the case being dealt with. It is of importance to eliminate, so far as possible, errors lying at the root of the comparison. For example, the comparison of a beam of symmetrical section with another of unsymmetrical section by use of the ordinary beam formulæ may produce very large errors. Again, errors often arise through want of proper consideration in cases of combined normal and shearing stresses. The effect of altered flexibility in a proposed arrangement often causes an entire change in the basis of comparison, and is generally uniformly neglected. Recent experimental work by Lilly on columns and Bach on flat plates was referred to. In connection with the latter subject comparatively little is known experimentally for rectangular plates fixed at the edges, and Dr. Thearle announced that the committee of Lloyd's Register had made a pecuniary grant to the author of the paper to assist in enabling further experiments to be carried out.

The acceleration in front of a propeller is the subject of a paper, in which Dr. R. E. Froude resists the inroad which a propulsion paper read by Prof. Henderson last year makes upon Dr. Froude's paper of 1889. The principal purpose of the latter was to prove from hydrodynamic theory that, in so far as the fluid acceleration by which thrust is satisfied may be treated as external to the propeller, one-half of that acceleration must take place before the propeller in obedience to defect of pressure in front of it, and the other half after it, in obedience to excess of pressure behind it. Prof. Henderson's paper of last year purports to prove, also from theory, that the precedent acceleration cannot possibly contribute to thrust. In the present paper Dr. Froude reasserts his theory, together with such further considerations as appear to be called for by Prof. Henderson's paper.

Herr H. Frahm contributes a paper giving the results of trials at sea of his anti-rolling tanks. Reference has already been made to Frahm's arrangement in NATURE. When in full action, the tanks on the ss. *Ypiranga* and *Corcovado* exert a turning moment of 2790 foot-tons, thus counteracting wave impulses of equal turning moment. In order to obtain equal efficiency in damping out rolling, the same turning moment ought also to be exerted by any other anti-rolling device, such as a gyroscope, which might be fitted to these ships. It is doubtful if it will be possible to develop the gyroscope sufficiently. The ss. *General* (13,620 tons loaded displacement), of the German East African line, started on her maiden trip at the beginning of March. When crossing the Bay of Biscay, she encountered a storm which made her roll 14° on either side when the tanks were out of action. This was reduced by 7° or 8° when the small fore tank was put into action, and with both tanks in action, the rolling was reduced to 3° in either direction. A large working model was shown in the library of the Royal Society of Arts. The ship was set rolling in a tank by means of an electromotor, operating on the model by means of a very flexible flat spring. The model showed very clearly the efficiency of Frahm's tanks in reducing rolling.

Prof. E. G. Coker describes his optical method of investigating stress in plates of variable sections, and gives some applications to ship's plating. The method has been already noted in NATURE, and it may be now added that the author has developed a method of obtaining the stresses quantitatively. This may be done by subjecting a standard test-piece to such a degree of pull or push that the colour produced agrees with that at a desired point in the body under examination. Or by a method modified so as to get rid of the necessary judgment in matching colours; this modified method may be used in all cases of pull or push stresses, and consists in arranging a simple pull or push member in the same field of view as, and immediately in front of, the object under examination. To determine the stress at any point, the reference member is loaded until the original dark field produced by the optical arrangement reappears. When this happens, the stress in the reference member is the same as that at the point considered, and no correction is required for the alteration in thickness produced by the stress, since both test pieces are in exactly the same condition.

STATE SURVEYS.[1]

THE true economy of executing land measurement of the highest precision as a control upon more detailed work, which can then be done more quickly and at less cost, is now generally admitted, and wherever the area is large such control work is carried out by a central administration for the use and assistance of local surveys. Methods will vary in different areas and with the special object in view, but such coordinated work on a large scale has great advantages over small scattered areas in which work is carried on independently.

(1) The operations of the Survey of India during the twelvemonth ending September 30, 1909, are described in the report which has just been issued. Primary triangulation was carried on in Beluchistan, Kashmir, and Burma over an area of 9600 square miles, besides a certain amount of building and selecting station; the average triangular of three groups completed were 0·41″, 0·6″, and 0·47″. The 10-foot standard bar A having returned from Sèvres, whither it had been sent in 1908 for comparison with the international metre, was recompared with the secondary standard bar of the Survey, and the results show that it is

[1] (1) "General Report on the operations of the Survey of India." By Col. F. B. Longe, R.E. (Calcutta, 1910.)
(2) United States Geological Survey, Washington. Bulletins 434, 437. Spirit Levelling, 1896 to 1909.
Bulletin 440. Results of Triangulation and Primary Traverse, 1906-8.

improbable that any change took place in its length between the time that it left India and its return from Sèvres, so that the value of bar A, viz. 3047·996 mm. at 62° F. in terms of the international metre, is thoroughly trustworthy. Pendulum work was carried on in the western tracts of the Sátpurá hills and the Vindhyan plateau as an investigation of the variation of gravity in the northern portion of peninsular India, and at seven stations, situated at from 750 feet to 2100 feet above sea-level, excesses of gravity were found. At twenty-eight stations above 750 feet hitherto observed gravity has never been in excess, so that dissimilar conditions in peninsular and extra-peninsular regions seems to be indicated. Subsequent seasons' work is being extended over Rajputana and the Sátpurá hills to the Gangetic plain. Tidal records from nine stations, Moulmein being one which was re-established, and nearly 1100 miles of double levelling, occupied a portion of the staff, while the Magnetic Survey working in Burma completed the preliminary survey with a total of 1255 stations.

Some specially disturbed areas were surveyed in detail, and this work is being continued. Heavy prolonged rain at Dehra Dun eventually forced its way into the magnetograph room, and, rising within an inch of the top of the driving-clock pillar, necessitated the removal of the instruments on August 15, which were replaced a month later. The Topographical and Forest Surveys also completed the survey of a large area of country. In cartographic work, the results of the reorganisation of the drawing, engraving, and printing branches which was carried out since 1906 are now to be seen, and the publication of standard map-sheets has kept pace with the survey and drawing, besides there being a considerable increase in outturn. A specimen sheet of the 1 : 1,000,000 map, the strategical map of India, is given, containing the region round Bombay; roads, railways, and boundaries are strongly brought out, but the relief is shown by shading, which renders main features prominent, and by comparatively few inscribed altitudes.

(2) The Bulletins of the United States Geological Survey, which deal with higher surveying, furnish the final results of work done in the field after all corrections have been applied. The numbers stamped on the bench marks in the field represent the elevations to the nearest foot above mean sea-level as determined by unadjusted levels in the field, and those who require a higher accuracy than 2 feet must consult these bulletins or apply to the offices of the Survey. The levelling is classified as precise or primary according to the accuracy of method and precision of the instruments employed, and lines are run both forward and backward in the former case, but in one direction only in the latter. The allowable limits of error in feet are respectively $0{\cdot}017\sqrt{D}$ and $0{\cdot}05\sqrt{D}$, where D is the distance in miles. In the bulletins the position of each bench mark is described and its altitude given to 0·001 foot for both classes of work.

The results of triangulation and primary traverse are likewise given in periodical bulletins, which not only give the description of each station, its mark and reference mark, and geographical position, but also the azimuth, back azimuth, and the logarithm of the distance from it in metres of all points observed from it. An interesting map of the United States is included showing the astronomic location and primary control up to January 1, 1909. While much has been accomplished, large areas remain along the 101st meridian, in the Southern States, and many other parts to be completed.

THE STANDARDISATION OF COLOURS.

UNDER the title of "International Rules for the Specification of Colours," Mr. Hans-Jacob Möller has reprinted an essay by him from the Journal of the Danish Apothecaries' Association (*Archiv for Pharmaci og Chemi*, November 14, 1910) showing the importance of having an international scheme of colours so as to enable reference to be made to a definite tint on a definite scale, and recommending as the most useful and most practical scheme of the kind that drawn up by Klincksieck and Valette, a scheme based upon the original system drawn up by Chevreul. There can be no doubt that such a colour scheme, recognised throughout the scientific world, would be of great practical value. For example, to take a very obvious instance, a large number of chemical reactions in connection with organic substances, such as dye-stuffs, depend upon colour changes, and if it was possible to describe these colour changes in accurate language, it would be of great practical value to the chemist.

When we come to the departments of pigments and of dye-stuffs, it is obvious that there, too, a definite recognised colour scheme would be of great practical value. It would, however, probably be better, if once a colour scheme was decided upon, that it should be reproduced in some permanent material such as coloured glass, so as to give a definite standard for reference at any future time, as a colour scheme which is merely lithographically printed may alter owing to fading of the colours, and if an attempt is made to repeat it, it is seldom that pigments can be twice reproduced with exactly the same tint.

On the other hand, an attempt to refer to definite lines on the spectrum is difficult in practice, as the use of the spectrum in this way for the matching of colours is not very easy, and it is not a satisfactory method. Mr. Möller does not refer to Lovibond's work on this subject and his scheme of coloured glasses. The present writer has found the Lovibond tintometer most useful and capable of very accurate matching, though the Lovibond standards are purely arbitrary. An arbitrary scheme seems the only possible one, and therefore, as Lovibond has devoted so much ingenious labour to the making and matching of his coloured glasses, there is a great deal to be said for defining tints by means of his tintometer, such a tintometer being kept as a standard of reference. Whatever may be determined, however, as the best practical solution of this question, it is certainly time that something of the nature of an international colour scheme be adopted, so that there should be no difficulty in referring to a definite scale and number in describing any colour.

A. P. Laurie.

DIET AND DEVELOPMENT.[1]

THE main impression left by a perusal of this exhaustive report upon the diets of labour convicts in Bengal jails, referred to below, is that the Indian Government has been well served in this matter, and has now in its possession advice derived so judiciously from soundly organised and ably conducted investigations as to justify what, on weaker evidence, might have seemed a parsimonious procedure, namely, some limitation of the too ample dietaries of these prisoners. The author may be said to have proved that their vegetarian diet, such as is the common food of the native population, has been provided in quantity so large as to escape digestion. No one will find reason to doubt his statement that this undigested material gives occasion to various forms of distressing trouble whilst in disordered transit through the alimentary canal of its consumers; not that this point is new, but that the condition has been very definitely shown as existing in this special and important case.

It would seem that, prior to this investigation, the diets had been arranged so as apparently to display the same "protein value" as a European diet. In the effort of imitating the heavy labour diet of English prisons with combinations of the native food-stuffs, meals of extraordinary bulk have been provided. Whereas, when added in small quantity to the varied constituents of a European meal, similar food-stuffs may yield so much as 80 per cent. of their contained protein for absorption into the tissues of the body, the author has shown that often no more than 50 per cent. is absorbed from them when found as the main constituents of a bulky meal, and this notwithstanding the fact that bulky meals are characteristic of the district, if to a somewhat smaller degree than within its jails. He has also proved that a certain ascertained diminution in this bulk, accompanied by an apparent diminution in the protein value of the diet, is always the

[1] "Investigations on Bengal Jail Dietaries, with Some Observations on the Influence of Dietary on the Physical Development and Well-being of the People of Bengal." By Capt. D. McCay, I.M.S. Pp. iv+226+15 charts. (Calcutta: Government Printing Office, 1910.) Price Rs. 2.6 on 4s. 3d.
(Scientific Memoirs by Officers of the Medical and Sanitary Department of the Government of India, New Series, No. 37.)

cause of an actual increase in the amount of protein absorbed, and has shown that some improvement in condition attends this alteration. His work promises, therefore, to be in a very real sense of economical value to the Government, indicating a better maintenance of health on wisely diminished rations. This statement also applies to his study of the salt requirements of these diets, which lead him to the conclusion that more salt is supplied than is useful, and that the excess is detrimental.

The author has carefully studied changes following an increased absorption of protein from the diet, and presents an admirable case for discussion alongside the valued contributions of Chittenden. He has enlarged his presentation of this case by reference to the habits of the different native races within his view. According to him, these races may be arranged in a series, in which virile characteristics vary directly with the protein value of the diet, and are greatest where, as amongst flesh-eaters, this value is at a maximum. Carnivorous man sets to his work with zest, and is prepared to labour strenuously, and, if need arise, fight for life. The vegetarian spends a gloomy existence, embarrassed by an internal tangle of cellulose, and is swept off by feebly resisted disease. Some of the evidence offered in support of this contention is not of the same value as that in the remainder of the report, but it is highly interesting, and has been usefully published.

Prof. McCay is to be congratulated upon a report that should be found in every library of physiological literature. The opportunities provided by such a systematic observation of human beings under very precise control are great, and have been well utilised.

J. S. MACDONALD.

RECENT PROGRESS IN AËRONAUTICS.[1]

THE sudden development of the art of flying which has come upon the world during the last few years may be classed as one of the most extraordinary events in the world's history. We have had far-reaching inventions introduced before, such as the railway, the telegraph, the telephone, the motor-car, and many others, but all these have gradually developed, have sprung from small beginnings, and often it seemed doubtful whether they would ever develop into utility of real importance. With the flying machine it is different. True it is that the advent of such an apparatus has been foreseen, not merely for some years, but for centuries. The inception is very old. Like the sailor's story to his incredulous grandmother of the flying-fish, so a hundred years ago no one would have been dumbfounded if one had prophesied that men would fly, although one would have been accused of talking nonsense had one foretold that we could talk along a wire hundreds of miles long, see bullets embedded in the lungs, or be able to reproduce a song sung by one departed. We dare not at present hazard a guess as to what the flying-machine may eventually develop into. There are still those who think it will never be much more than a curiosity, but there are others who believe it will soon become our usual mode of travel, and that railways, steamboats, and motor-cars will have to take quite a back place in comparison.

My object to-night is not to give a full history of the navigation of the air. That is getting into a big subject that would occupy a long time to properly relate. Nor is this to be a very technical lecture; I propose now merely to refer to the latest developments—to trace some lines of thought which I hope may serve as a basis on which my hearers may build more solid structures for the improvement of the navigation of the air.

Aërial machines have been classed under two headings, known as lighter-than-air and heavier-than-air. I do not purpose going very deeply into the question of the first class, because I am inclined to think it is a subject of comparatively little importance, the latter having made such very much greater progress of late, and being able to effect almost all that the dirigible is designed to do and with greater ease and efficiency, that it seems likely to entirely oust the former.

A few words, however, on gas-borne vessels may be desirable to point out how they have been evolved, and in which direction improvements may be looked for, should their development be considered advantageous.

Balloons.

First we have to consider that simple contrivance the balloon, by means of which men have, for the last century and a quarter, been able to rise in the atmosphere and drift with the wind wheresoever it listeth. It is a remarkable fact that, notwithstanding the great hopes it raised in early days, scarcely any improvement has been made in this contrivance during a hundred years of practice. This refers to the simple balloon. Almost immediately after its invention suggestions were made to form it as a long vessel and propel it with screws, and though to-day we have the practicable dirigible balloon, it is probable that no invention has been longer in developing. Step by step it has grown from the ideas of Meusnier, through the crude machines of Giffard, de Lôme, Tissandier, to the first successful vessel, that designed by Colonel Renard, nearly thirty years ago. Though much progress has been made since, it has always been slow.

Santos Dumont evoked much public interest with his little vessels; Count Zeppelin certainly made a big step forward with his large rigid-framed leviathans, while Parseval, Gross, Julliot, and others have further developed the invention. From Giffard's steam engine of 3 horse-power to the 500-horse motor of the Siemens-Schuckert, every variety of engine has been tried, continually increasing in power.

Nor does it appear that any very revolutionary advancement is likely to be effected in the future with dirigibles. We may hope to go on making each vessel a little better than the last, much in the way in which steamships have progressed.

Undoubtedly the main path along which improvement is possible and desirable is that of speed. So long as an aërial machine is only able to progress at a rate not much above that at which the wind usually blows, it is bound to be very dependent on the ever changeful weather. A dirigible can never be considered really practical (in this country at least) until it is capable of travelling at, say, 40 miles an hour. This is a speed not yet attained by any dirigible. The wind at one or two thousand feet up frequently blows at 30 miles an hour, and not only must we be able to make head against this, but we ought to be able to progress fully 10 to 20 miles in the teeth of it. Now, considering for the moment solely the lighter-than-air machine, given a certain weight of engines, since buoyancy is dependent on displacement, we cannot make the vessel any smaller if it is to lift the weight. In order to increase its speed, then, presuming the shape and the surface and fittings to be such as to offer a minimum of resistance, there seem but two possible means. One is to make engines more powerful for their weight, and progress in this line seems moving rapidly. The other is to increase the size of the gas-holder. As the volume is enlarged the lifting power (and hence ability to carry more powerful engines) is increased at a greater rate than is the cross-section and surface, and consequent resistance. So we get the tendency to construct huge machines ever growing larger. This size, however, is one of the greatest practical drawbacks to the employment of such vessels. It is true there is plenty of room in the sky, and if the machines had to remain always aloft there might be no difficulty. But to be of use they must come to earth, and the enormous bulk has to be held stationary against any wind that may happen to blow. This is exceedingly difficult, and necessitates the use of sheltered harbours and sheds to house these monstrous structures, which implies vast expense.

There is, however, yet another means by which it may be possible to increase the speed without adding to the bulk. It is one that has often been suggested, several times tried on a large scale, but does not seem to show signs of general application. I refer to the use of horizontally disposed surfaces known as aëroplanes. If we have an apparatus travelling at, say, 30 miles an hour, and we add such devices, it will be found that they give a very considerable extra lift, and this may be utilised for raising an extra weight of engines. By adding to the propulsive power we both increase the speed, and thereby

[1] Paper read before the Junior Institution of Engineers on April 11, by Major B. Baden-Powell.

the lift, which enables us to carry still further weight of engines, and so *ad infinitum*. This soon leads us on into another kind of appliance, for if we then want to increase our speed further, all we have to do is to reduce the resistance. This can now easily be done by lessening the size of the gasholder. Having thus gained more speed and got more lift out of our aëroplanes, we can still further curtail the volume, and so we go on until we find we have no gas left, and yet our machine progresses at a greater rate than ever! Therefore, why start with the troublesome gas bag at all!

Aëroplanes.

Six years ago such a thing as a real flying machine was unheard of. We had seen Maxim's great structure running along its rail. We had rumours of Ader having done something in secret in France. We had read of Langley's steam-driven model going for three-quarters of a mile. But it was in 1905 that accounts began to leak out of real flights having been accomplished by the Brothers Wright in America. In the following year Santos Dumont gave the first public demonstrations of a man being lifted off the ground by such an apparatus. In 1907 Farman made a number of short flights up to about half a mile; Blériot and Esnault-Pelterie also made some "hops." It was not until 1908, however, that anything approaching real flight was shown to the world, when Henry Farman and Delagrange accomplished what was considered extraordinary performances on a Voisin machine, and when later in that year Wilbur Wright set up his machine in France, while his brother Orville flew (with such unfortunate results) in America; the introduction of practical flight may then be said to have come about.

In order to realise the great progress in the art of flying from that period to now, some two years and a half, I may quote the "records" accomplished:—

	Duration in the air. Hrs. Mins.	Distance travelled. Miles.	Altitude attained. Feet.	Speed Miles per hour.
1905	0 36	24	—	40
1906	—	$\frac{1}{4}$	—	25·8
1907	0 $\frac{3}{4}$	$\frac{1}{2}$	19	33·7
1908	2 20	$77\frac{1}{2}$	328	40·5
1909	4 17	145	1,560	48
1910	8 12	365	10,500	65·5

During 1909 much progress was made. In England, Cody made some creditable flights; in America, Glenn Curtis, McCurdy, and others; while in France quite a number of aviators budded forth. In 1910 all records were beaten out and out, and very much was accomplished.

It is thus evident that immense progress has been accomplished in flying. Now let us turn to the machine itself and see in what essentials it has been improved. A vast variety of machines have been built and even tried, but of those differing much from what we may call the standard types, very few have accomplished any success.

I take as the standard types the Wright (with large elevators and no tail), the Farman or Voisin (with small elevator and big tail), and the Blériot monoplane (with no elevator in front, but tail behind); most other machines are but modifications of them.

Wright Type.—The original Wright machine has undergone three important modifications, which render the latest pattern a completely distinct type from the first machine. First, wheels have been applied, so that it is now capable of rising directly off the ground after a preliminary run, and is not dependent, as it originally was, on being drawn along a rail by falling weights, so as to give it an initial impulse. Secondly, a horizontal tail has been added, which has greatly improved the inherent fore and aft stability. Finally, the front biplane elevator, which seemed so essential a feature, has been done away with. A machine of smaller area has also been produced, the span being only 22 feet, or nearly half the dimensions of the original machine. It is now reported that the Wrights are building a machine to carry eight people in a closed carriage, with a 100 horse-power motor.

The Cody biplane is very similar in general design to the original Wright, at first having no tail (though one has been added recently), the main difference being that it has only a single propeller, and has ailerons placed between the planes at the outer ends to effect the same as the warping of the Wright planes. The details of arrangement of the frame and wheels are somewhat different, and the elevator in front consists of two independent planes side by side. It is a large machine, having a span of $46\frac{1}{2}$ feet, and the upper planes being $8\frac{1}{2}$ feet above the lower.

Voisin and Farman.—To follow up the development of the Henry Farman and Voisin types, the two must be taken together, since the former was but a modification of the latter.

The first successful Voisin machine consisted of a biplane divided into "cells" by vertical walls. The span was about 34 feet. It had one biplane elevator and a very large cellular tail. The latter was soon reduced in size to a span of 8 feet.

The Henry Farman biplane, which was evolved from the Voisin type, the main difference being the omission of vertical planes and the addition of flaps for transverse control, has not altered very materially. The size of the box tail has gradually been reduced, and in the latest machines the upper plane is made wider than the lower by the addition of extensions. Both H. Farman and Grahame White have recently tried machines of much smaller area. The former has planes of 150 square feet each, and has lifted at the rate of $6\frac{1}{2}$ lb. per square foot. There are a number of other machines of similar build. The Curtiss differs in having ailerons instead of flaps, and the Maurice Farman, the Sommer, the Bristol, and the Howard Wright differ only in small details.

Blériot.—The Blériot monoplane, which underwent a great variety of modifications to start with, has now settled down into the well-known type with a span of about 30 feet, with a fixed tail behind fitted with inclinable planes on each end. The latest type of two-seater is of 36-foot span, with a trailing flap tail.

The *Antoinette* monoplane is not very different in its general characteristics. It is much larger, and the "aspect ratio" or plan of the wings shows a greater span for length. Flaps are attached to the trail of the outer ends of the planes, and a fixed horizontal tail, or "empennage," is arranged at the end of the body.

Santos Dumont's *Demoiselle* monoplane is much the same type as the Blériot, but has always been of smaller size. Other features are that the man is underneath, and the engine is placed on top of the planes, so as to raise the centre of gravity, which would otherwise be very low, and to be able to couple the $6\frac{1}{2}$-feet diameter propeller direct to the shaft.

Other Types.—Other types of successful machines include the Breguet, which, though a biplane, has all the other characteristics of a monoplane, viz. propeller in front of all, with the engine behind it, fish-shaped body, and cruciform tail behind. This has proved very satisfactory, having recently taken up as many as twelve people. A new pattern of Bristol is of similar design.

The Dunne biplane and monoplane, with redan-shaped planes and no elevator or tail, for which a large degree of automatic stability is claimed, have achieved considerable success.

The *Valkyrie* monoplane, which may be considered as a separate type, having its elevator, as well as a small fixed plane, in front, and the propeller behind the main planes, has also done well.

Taking a general view of the recent developments, we are confronted with strange anomalies. Some inventors, such as the Wrights, have discarded the front elevator, though this does not seem to prove it undesirable, for others have adopted it. While some Farmans have been improved by the addition of more surface, yet small machines of nearly half the area have proved highly satisfactory.

One of the most surprising results of a study of these changes in design is that it seems possible to alter the disposition of the surfaces of a machine in quite a marked manner, and yet there is but little difference apparent in the ability to fly. It becomes very puzzling to the mathematician and theorist who wishes to investigate the subject, and to ascertain the whys and wherefores, when he reads of areas being reduced without detriment, of eight and even twelve men being carried on a machine designed

to carry only one or two, of a machine fitted with a 50 horse-power engine flying faster than one almost exactly similar having a 100 horse-power engine. It all seems to show how very little we know of the principles which underlie the matter, and how much really careful experiment and research are needed if we are to go by anything more than rule of thumb.

Now that a certain amount of experience has been gained, we can get at some idea as to which type of machine is generally pronounced the most satisfactory. It is perhaps curious that two types so different as the Farman biplane and the Blériot monoplane have performed so similarly, and there does not seem to be any decided preference among flying men between the two. The following figures of the machines on which certificates had been gained in France last year give some idea of the popularity:—

93 Blériot monoplane, 81 H. Farman biplane, 37 Antoinette monoplane, 30 Sommer biplane, 26 Voisin biplane, 16 Wright biplane, 15 Hanriot monoplane, 9 M. Farman biplane, 20 on other biplanes, 17 on other monoplanes (besides 10 others not specified), that is, 162 monoplanes and 182 biplanes.

Of British-owned machines, according to Jane's "All the World's Airships," there are (or *were* five months ago):—

34 Blériot, 14 H. Farman, 6 Voisin, 8 Wright's, 5 Sommer, 4 Antoinette, 1 Demoiselle (besides small numbers of various English makes).

This list is, however, not very trustworthy as an indication, as many of these machines have scarcely been tried, and many others (not included) have done good service during the last four or five months.

Automatic Stability.—A great deal has been said and written on this subject. Before practical flight had been attained, it was often thought that it would be necessary to apply some controlling mechanism actuated by a pendulum or gyroscope, so that when the machine tilted over it would be automatically forced back. Practice has shown that such an arrangement is quite unnecessary. We still hear of projects of this nature, but it is evident, not only from the performances of actual machines in the hands of expert aviators, but also from uncontrolled models, that a properly designed and properly balanced machine is quite stable by itself.

Motors.—The subject of motors for aërial work is perhaps rather beyond the scope of this paper, but since so much depends upon the motive power—indeed, the advent of the successful aëroplane may be said to have been entirely due to the invention of the petrol engine—I must refer briefly to it.

The chief notable feature in this line is the very general adoption of the Gnome rotary motor. This peculiar engine, which, of course, consists of seven cylinders radiating from a central shaft, which spin round forming a fly-wheel, and very efficiently cooling themselves by their rapid motion through the air, was at first looked upon as an impracticable freak. In 1909, however, it was fitted to several machines, and at once proved itself trustworthy and superior to all other motors for the purpose. Recently quite a number of engines of somewhat similar design have been brought out, and some of them, such as the Buckman, seem likely to prove even more efficient.

Meanwhile, several British-built engines of more ordinary design have come to the fore, notably the Green, with four water-cooled vertical cylinders, the N.E.C., a two-stroke motor, and the E.N.V., and several others, but for one reason or another these do not seem to be so popular with practical aviators.

Future Developments.—It is, of course, extremely difficult to foresee in which direction aëroplanes are likely to develop. There is, however, here again one of those what I may call "reciprocal" situations such as I have referred to with regard to balloons. The tendency seems to be to make the planes smaller. By this decrease the weight is lessened as well as the resistance. By lessening the resistance the machine should travel farther, and the decrease of weight of planes should enable a heavier and more powerful engine to be carried, and thus speed again increased. By travelling faster we obtain more lift, and can therefore further cut down the size of the planes. So we go on, making the machines smaller and the speed faster; and who can say where the limit may be?

Other types of machines have often been suggested, notably those of the wing-flapping species, and those with vertically acting screws. Seeing the success which has attended the simple aëroplane, I think it is doubtful if any other form will supersede it, but I have long been of opinion that some combination may prove advantageous. For instance, it is possible to arrange for vertically thrusting screws to assist in starting the machine, and it seems quite probable that a propeller on the flapping-wing principle may prove highly efficient.

THE AUSTRALASIAN ANTARCTIC EXPEDITION.[1]

AUSTRALIA and New Zealand have always been anxious for further knowledge of the great frozen continent lying to the southward of them. Because the Ross sea area is more conveniently situated to the south geographic pole, most expeditions to the Australian quadrant have wintered there. This has led to the neglect of the great coast-line westward of Cape Adare. Our information regarding it is very fragmentary, and for the most part untrustworthy. Properly equipped, an expedition to this region should have no difficulty in achieving great geographical successes. In the words of Dr. H. R. Mill, "It is time, at any rate, that someone should revisit the lands discovered by Biscoe, Balleny, D'Urville, and Wilkes. . . ."

Lying within wireless telegraphic distance of our borders, this region has a special call upon Australians. Alive to the value of scientific data there massed waiting to be collected, I have ardently sought for an opportunity to reap the harvest. Captain Scott's programme was too full with the determined efforts in view, upon the south geographical pole and King Edward VII. Land, to accede to my request to be landed this year with a party at Cape Adare. It was then that Sir Ernest Shackleton proposed to raise the necessary funds, and, with myself in charge of the scientific work, to attack the whole coast-line between Cape Adare and Gauss Berg. The plans were published in the Press on March 19, 1910, and repeated later in the year. Eventually Sir Ernest Shackleton handed over command to me.

Until the last fifteen years, though touched upon as early as 1820, only about seven expeditions, excepting whalers in the areas south of America, have come within sight of the continent. It was not until 1898 that the first Antarctic night had been experienced; even to the present day but four expeditions have wintered on the continent, and their contributions refer only to isolated spots of the 8000 miles, more or less, of coast-line. It is gratifying to note the successes which have attended recent assaults upon the unknown, and we can confidently look forward to the complete unravelling of the broader features and secrets of Antarctica within the next three years.

The Antarctic Continent.

Conclusions of any but local value based on the data available are obviously liable to prove in error, but will always serve a useful purpose in directing the attention of explorers to possible contingencies. The inadequacy of the data available is comprehended when we find, based upon them, several entirely different views regarding the geomorphology of the South Polar region. There is, nevertheless, a general agreement regarding the seaward limits of the land and the permanently attached ice. That is to say, we can now guess approximately the limits of southward navigation—where ships must be brought up either by land or barrier ice. Assuredly considerable portions of this coast-line are no more than barrier ice—marginal shelf-ice of great thickness—which in the recent past may have been of greater seaward extent, and in the future may retreat even hundreds of miles before the rocky coast-line is revealed. These barriers originated from the land glaciers, and are partly aground, partly afloat. It appears probable that the immense thickness of nearly 2000 feet is sometimes reached. In such cases the barrier ice, though afloat,

[1] From a paper read before the Royal Geographical Society, on April 10, by Dr. Douglas Mawson.

plays the *rôle* of land, and is charted as the margin of the continent.

Concerning the topography of the interior, all is speculation except in the vicinity of Captain Scott's and Sir Ernest Shackleton's exploits.

Thus it is that some hold the view of a continuous high land from Graham's Land to South Victoria Land—a continuation of the Andean chain; others regard the possibility of a great trough-subsidence, continuous from the Ross sea to the Weddell sea, isolating an eastern and a western Antarctica. Yet another view is that Enderby Land is part of a third isolated mass. There are many grounds in support of the existence of a trough between the Victoria Land massif and the Andean continuation of Graham's Land. Granted its existence, it will be still uncertain whether this depression sinks below sea-level, or is merely a topographical feature of the land. The existence of a passage below sea-level appears quite unlikely to me. Nordenskjöld and Gunnar Anderson have shown how the highlands of Graham's Land must be regarded as a continuation of the Andes. Possibly, further to the westward, this folding has been responsible for land trending towards King Edward VII. Land, the presence of which has been inferred by Charcot, and does not participate in the piling up of the mighty ranges which girdle the south geographic pole.

This may ultimately prove to be correct, for the geology of Victoria Land corresponds with that of Australia and Tasmania, whilst, in the same region, Andean types are represented further to the eastward amongst the Pacific islands.

Another point of correspondence is that South Victoria Land is elevated *en bloc*, and not subject to the contortions of folding illustrated in the Andes. I am not by any means the first to entertain this idea of an inverted South America. According to it, the highlands of Graham's Land are continuous with the mountain ranges of South Victoria Land. To the westward of this main range there is a great plateau, in part as much as about 10,000 feet in height, eventually sloping to the Indian and Atlantic oceans. Eastwards, on the Pacific side of the range, there is a precipitous scarp. We have no means, as yet, of telling whether this lower area is barrier ice with occasional islands, or is extensive undulating land.

Between Gauss Berg and Graham's Land, on the Atlantic ocean side, it is likely that most of the sea-front will be occupied by barrier ice; Enderby and Kemp lands, therefore, may be no more than islands.

The consanguinity of the lavas of Gauss Berg and the Ross sea downthrow area is suggestive of a similar downthrow in the direction of the former; it is possible, therefore, that a considerable indentation lies west of Gauss Berg.

According to present views, the Antarctic continent has an area of about five million square miles, the major part of which is a plateau of great height. Geographers are generally agreed, at any rate, that the main land mass of the Antarctic regions lies in the Australian Quadrant. This has been independently arrived at from theoretical considerations by Mr. E. A. Reeves, who has discussed the subject of distribution of land and sea as judged by the deflection of the lines of magnetic force.

Glimpses only of the past history of Antarctica are yet known—fragments gleaned from the analysis of scientific data to hand. We know that there were periods when ice was almost unknown, when great formations of water-deposited beds accumulated, associated with coal-bearing strata; these beds have their exact prototypes in Tasmania—in fact, where Tasmania leaves off South Victoria Land begins. We believe that in not long geologically remote times the intervening 1500 miles became engulfed; this conclusion is arrived at by an entirely separate line of argument proceeding from the evidence supplied by fossil and living forms of life.

Australian and New Zealand types show a remarkable affinity with those of South America and South Africa. This striking similarity in variety and range is exemplified not only in the bird life and mammalia, but also in the crustacea, amphipoda, mollusca, galaxias, and others. The similarity extends to the flora also. To the casual observer the connection is most noticeable in regard to the birds and mammals. We find parrots and struthius birds of the ostrich type common in these southern lands. Considering the marsupial mammalia, such occur at the present day in the Australian region and in Central and South America. Of the two sub-orders, Polyprotodontia and Diprotodontia, into which the marsupialia are divided, the Diprotodontia, which are the more primitive, are essentially Australian, as shown by the abundance of their fossil remains. The fact, however, that a representative of this class is now living in South America is strong evidence of a land connection, unless an independent and convergent process of evolution is regarded as possible. Further, the fossil evidence is absolutely in favour of a continuity between South America and Australia—as, for instance, may be mentioned amongst the extinct marsupial fauna of Patagonia, the Prothylacinus, which is essentially identical with the Tasmanian tiger. All this evidence confirms the theory of connection between the southern lands by way of Antarctica.

On the other hand, there is no line of argument founded on fact which can be urged to support the view of immigration by way of Asia. Suppose, for instance, that the marsupial fauna had come to Australia from Asia; then we should expect to find the types most numerous and most generalised in Northern Australia and Asia. Identically opposite is the case, and in the whole of Asia no living or fossil marsupial has ever been found.

The evidence is conclusive, therefore, in the minds of men of science, that in the not long (geologically) past there existed a habitable Antarctic continent with rays stretching up to meet with what are now Tasmania, South America, New Zealand, and South Africa. With regard to the relative dates at which these countries became severed from the southern continent, the evidence shows that with South Africa was the earliest and loosest. New Zealand, though possessing many of the features of Antarctic flora and fauna, never received a marsupial population, and its final separation is thereby allocated to the early Tertiary times. Australia, then separated by the formation of Bass strait, and more recently Tasmania and South America, have become isolated by the engulfment, due to diastrophism of the land bridges connecting both with the Antarctic continent.

Much of the strata of Southern Australia are composed of the *débris* of this lost land. To the south of Australia, where now is ocean, were highlands, providing an abundance of material shed northward into what were then lowlands and marine areas. Volcanic activity on a large scale, remaining even to the present day in isolated spots, attended the separation of these land masses. Finally, an ice age of almost unprecedented severity overwhelmed the residual Antarctic continent, and swept every trace of life into the southern ocean.

The Plans of the Australian Expedition.

We hope to have a complement of fifty men—ship and land party—and proceed south from Australia about the close of this year. Practically every member of the land party will be a specialist in a particular branch of science. Most of the recruiting will be amongst the graduates of the universities of Australia and New Zealand.

It is our intention to land several parties with stores and huts, to winter between Cape Adare and Gauss Berg, and the ship will return to Australia and New Zealand for the winter, though not remaining idle. It had been our intention of dropping a few men at Cape Adare, for that is the easiest and most accessible landing on the Antarctic continent. The facilities there afforded of coal and stores left by Borchgrevinck's expedition would have further simplified matters. In the light of recent events, of course this must be eliminated from our programme. It is our special desire to accomplish a complete coast survey between the two points mentioned, and complete the magnetic charting of the region north of the south magnetic pole. The several wintering stations will simultaneously despatch coastal sledging parties on either hand, thus dividing up the task. A special journey will be made inland from our main base on the north coast to the south magnetic pole, thus completing, in conjunction with the former journey in which I participated, the crossing of that corner of South Victoria Land. For the rest, without entering into details, I may say that no branch of science will be neglected.

Before Australian meteorology is placed on a final basis—before the causes are known which produce the effects

observed—much more requires to be known regarding the circulation of the atmosphere in high southern latitudes. There are no other portions of our globe, excepting equatorial regions themselves, which influence so greatly the climate of the southern hemisphere than the Antarctic continent. It is a vast refrigerator condensing warm moist overhead currents from the equator and speeding them back at sea-level, frequently with hurricane velocity, much to the consternation of Australian shipping. All such irregularities in the regular anticyclonic cycle can be predicted by an observing station on the coast of Antarctica, southward of Australia. That the regular phases of barometric pressure in the Antarctic regions are the dominating causes that affect the climates of the southern temperate regions cannot be denied, and by their study we shall become more capable of predicting weather for Australia.

It is very desirable that a permanent meteorological station in connection with Australia and New Zealand be erected either at Adelie Land or to the west of it.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

Birmingham.—As an outcome of the recent increase in rate aid granted by the City Council, the University has drawn up a scheme for bringing facilities for higher education within the reach of the poorest scholars who may have the requisite ability. Twelve entrance scholarships, tenable for four years, are offered for competition at the forthcoming matriculation and intermediate examinations in July and June respectively. Candidates must have been resident within the city boundaries for at least one year, and must have attended one of the schools in that area. Competitors must reach such a standard as, in the opinion of the University, offers a reasonable prospect of a successful or distinguished career. Competitors may further apply for an annual grant (not exceeding 30*l.*) towards maintenance, on the ground that they are unable to avail themselves of such scholarships without a maintenance grant in addition. It will be interesting to see to what extent the maintenance grants increase the number of suitable candidates, for hitherto the number of entrance scholarships has been in excess of the number of properly qualified applicants.

It is officially announced that Dr. Theobald Smith will be the Harvard exchange professor at Berlin University during the academic year of 1911–12. Dr. Smith has held in succession the chairs of applied zoology and comparative pathology at Harvard, and is a member of the board of directors of the Rockefeller Institute for Medical Research.

The Council of the City and Guilds of London Institute has elected Dr. E. Frankland Armstrong a fellow of the institute (F.C.G.I.), in recognition of his original research work and his contribution to the advancement of the industry, in which he has been engaged since he gained the associateship of the institute at the close of his regular course at the City and Guilds Central Technical College in 1903.

The University Extension Board of the University of London has arranged a training course for lecturers to be delivered in the University buildings, South Kensington, in the Easter term. The course will consist of four lectures by Prof. John Adams on "The Art of Lecturing," four lectures by Dr. H. H. Hulbert on "The Delivery of Lectures," and six meetings for practical work. Each member of the class will have an opportunity of delivering a trial lecture, and will have the advantage of the criticism of Prof. Adams as regards material and arrangement, and by Dr. Hulbert as regards delivery.

SOCIETIES AND ACADEMIES.

London.

Royal Society April 6.—Sir Archibald Geikie, K.C.B., president, in the chair.—Hon. R. J. **Strutt**: The Bakerian lecture. A chemically active modification of nitrogen produced by the electric discharge. The leading facts established are:—(1) That pure nitrogen, from whatever source, subjected at a low pressure to the jar discharge, undergoes some modification which causes it to glow for a short time after it has been sucked away from the discharge. (2) The glow which is emitted while the gas returns to its normal condition is not destroyed by the removal of ions. It is weakened by heating, intensified by cooling. This seems to favour the view that it is due to the recombination of dissociated atoms. (3) The modified nitrogen acts on ordinary phosphorus, combining with it, and at the same time forming much red phosphorus. (4) It combines with sodium and also with mercury at a gentle heat (say 150° C.), forming in the latter case an explosive compound, and in each case developing the line spectrum of the metal concerned. It also develops the line spectra of other metals, probably combining with them. (5) It develops the band spectra of compounds, when these are vaporised in it, giving in many cases spectra of substances too unstable to be examined at the temperature of the Bunsen flame. (6) It attacks acetylene, and substances like ethyl iodide or chloroform, setting the halogen free when there is one, and combining with the carbon to form cyanogen. This is proved by the brilliant cyanogen spectrum produced, and by direct chemical tests, such as formation of Prussian blue. (7) It attacks nitric oxide, with formation, strangely enough, of nitrogen peroxide, a more oxidised substance.—A. **Holmes**: The association of lead with uranium in rock-minerals, and its application to the measurement of geological time.—Prof. E. T. **Whittaker**: The dynamical value of the molecular systems which emit spectra of the banded type. It is now widely believed that when the spectrum emitted by a luminous body is of the banded type, the small vibrators which give rise to the radiation are the molecules of the substance, as distinguished from atoms or ions. This result is applied in the main body of the paper in order to suggest a dynamical system, which is formed of two members in the same way as a diatomic molecule may be supposed to be formed of two atoms, and which has free periods of vibration related to each other by the same formula as holds in the case of banded spectra. This formula presents a certain peculiarity, in that the frequency of vibration occurs in it linearly, whereas in the equation for determining the free periods of dynamical systems in general the frequency enters by its square. It is shown that from this peculiarity in the radiation of a molecule certain inferences may be drawn regarding the dynamical character of the connection between the atoms within the molecule. It is shown that a somewhat modified mechanism would emit radiations connected by the same law as that which Balmer found for the hydrogen lines.

Royal Meteorological Society, March 15.—Dr. H. N. Dickson, president, in the chair.—Prof. H. H. **Turner**: What can we learn from rainfall records? The "periodogram" method has been applied under the superintendence of Prof. Schuster and the lecturer to the rainfall records of Padua (175 years) and Greenwich (90 years), besides Klagenfurt and Oxford (50 years), all periods between 20 months and 5 months having been examined, as well as some others. The resulting indications are not very positive, but include several features well worth further study, especially in the Greenwich rainfall, where periodicities of 597 days and 150 days (possibly a quarter of the former) seem to be fairly persistent, as well as a short one of 25 days; but these are not reproduced in the Padua records, at any rate not exactly. There are doubtful periods of 591 days and 147 days, which again are possibly related by the ratio 4 to 1. (The shorter periods near 25 days have not been investigated, as daily records are required.) It is possible that the periodicities change slowly with the latitude, in a manner suggested by the cloud belts on Jupiter.

Geological Society, March 22.—Prof. W. W. Watts, F.R.S., president, in the chair.—Dr. A. S. **Woodward**: Some mammalian teeth from the Wealden of Hastings. Mr. Charles Dawson has obtained two imperfect molars, apparently of Plagiaulax, from beds of grit in the Wealden near Hastings, and his associates in the work of exploration, Messrs. P. Teilhard de Chardin and Félix Pelletier, have found a well-preserved multituberculate molar of the form named Dipriodon by Marsh. These specimens are described.—A. **Wade**: Some observations on the Eastern Desert of Egypt, with considerations bearing upon the

origin of the British Trias. Phenomena observed in the Eastern Desert of Egypt, bordering the Gulf of Suez, are described. The origin of the mounds of igneous débris which flank the coastal hill-ranges is discussed. The distances to which fragments of igneous rock derived from these hills have travelled in Egypt are shown. The shore-sands are dealt with, and their origin ascribed to the breaking down of local rocks. In the marly beds connected with the shore-deposits, tiny dolomite-rhombs, similar to those found by Dr. Cullis in the Keuper Marls, are present. Some effects of wind-blown sand are detailed. The alteration of the calcium carbonate in recent shell-beds to gypsum is noted, and its significance with regard to the origin of gypsum-beds is pointed out. The characters of the massive older gypsum- and rock-salt deposits are described, together with the distribution and lithological changes in the beds when traced across the area. The origin of the gypsum series is connected with inland salt-lake conditions, and the evidence suggests that these conditions were contemporaneous with the Oligocene continental period in Egypt, and with the formation of the beds of the Fayûm in the Western Desert.—H. **Bolton**: Faunal horizons in the Bristol coalfield. The existence of faunal horizons at the collieries in the Bristol and Gloucestershire area, and in the Radstock area, has been determined. A measured section has been examined in detail, and four faunal horizons discovered. In every case the fauna was marine in character, and the series are all characterised by a fauna agreeing with the typical fauna of the Lower Coal Measures of the coalfields of the Midlands, and of Lancashire and Yorkshire. Species of Carbonicola are rare, while the cephalopod and fish fauna is poor. The second series of the Upper Coal Measures has yielded *Lingula mytiloides*, several species of ostracods, four species of Anthracomya, and scales of *Strepsodus sauroides*. *Coelacanthus elegans* has been found in the first series. In the Bristol coalfield the marine fauna undergoes no marked change in its upward range. Insect-wings referred to the genus Genentomum have been found at one horizon, while the rare phyllopod, *Leaia leidyii*, var. *salteriana*, hitherto only known from the Lower Carboniferous of Fifeshire, was found in abundance. The total number of species now recorded from the Bristol coalfield amounts to seventy-four.

Mineralogical Society, March 21.—Prof. W. J. Lewis, F.R.S., president, in the chair.—Prof. W. J. **Lewis**: Mr. Solly's observation of wiltshireite in 1903. Wiltshireite is identical with the mineral which Mr. Solly exhibited and described before the society, November 17, 1903, and subsequently named rathite α, but of which no complete description has yet been published.—R. H. **Solly**: Two new minerals from the Binnenthal, Switzerland. Both are probably sulpharsenites of lead, being lead-grey in colour and giving a chocolate-coloured streak; one, which is rhombohedral-diplohedral, and has an angle $111:100=38° 18'$, is probably isomorphous with trechmannite, while the other may be orthorhombic, the angle $100:110$ being $58° 18'$, but no measurable end faces were observed.—J. B. **Scrivenor**: Notes on cassiterite in the Malay Peninsula. Cassiterite from a mine at Gopeng contains ilmenite and magnetite, and is attracted by the magnet; it also occurs mixed with tourmaline pseudomorphic after an hexagonal mineral, probably quartz.—Arthur **Russell**: Notes on the occurrence of dundasite in Derbyshire and co. Galway, and of bertrandite in Cornwall. Dundasite was discovered at Mill Close mine, Wensley, Derbyshire, as snow-white spheres associated with greenockite, fluor, cerussite, calamine, &c., and at Clements lead mine, Carrowgarriff, near Maam, co. Galway, associated with allophane and cerussite, and bertrandite was found in platy crystals on old specimens of blende from Wheal Vor, Breage, Cornwall, and as trillings, measuring up to 4 mm. in length, on a specimen from Wheal Metal, Breage, Cornwall, which had been presented as albite to the British Museum in 1870; in the latter case the crystals were similar to those from Pisek, Bohemia, described by C. Vrba.—Dr. J. **Drugman**: Quartz-twinning. The possible varieties of twinning of quartz were discussed, with special reference to the rhombohedron type, a specimen of which was exhibited.—T. V. **Barker**: Crystallographic notes. Two new forms found on crystals of inosite confirm the hypohexagonal type of symmetry suggested by Fedorow. The rhombohedral modification of potassium nitrate, unlike sodium nitrate, does not arrange itself regularly when deposited on a cleavage piece of calcite; the crystals are very unstable, and rapidly pass into the ordinary orthorhombic form. A parallel growth of calcium chromate on the isomorphous mineral gypsum was obtained. New forms have been observed on urea nitrate which enabled the axial ratio $b:c$ for the first time to be calculated; the crystals have large birefringence, and, when grown in a drop, are nearly always twinned.

Physical Society, March 24.—Prof. H. L. Callendar, F.R.S., president, in the chair.—Dr. H. F. **Haworth**: (1) A sensitive thermo-regulator; (2) experiments on the measurement of electrolytic resistance using alternating currents. The "thermo-regulator" consists of a toluene thermometer with mercury platinum contacts in a capillary tube; these contacts operate, through a Siemens telegraph relay, an electromagnetic switch, which cuts in or out the heating circuit. On account of the very small current required to operate the relay, a fine capillary may be used, so ensuring a high magnification with low thermal capacity. Experiments were also shown illustrating the ease with which a bridge containing an electrolytic cell could be balanced by placing a variable self-induction in series with the cell and adjusting it and the resistance of the bridge simultaneously, as in Wien's experiments, except that a vibration galvanometer was used in place of the optical telephone originally employed by Wien. The author's deduction from his experiments was that the resistance of an electrolyte varies with the frequency of the alternating E.M.F. applied.—Prof. G. W. O. **Howe**: Oscillatory currents in coupled circuits. A demonstration was given by means of a double projection oscillograph of the currents in coupled oscillatory circuits. Each circuit consisted of a condenser, an air-core choking coil, and a strip of the oscillograph. The condenser in the primary circuit was charged and discharged by means of a commutator on the spindle of the oscillograph motor. The two circuits may be taken to represent the condenser circuit and the aërial of a wireless telegraph sending apparatus, the frequency being two or three hundred instead of a million. The currents in the two circuits can be studied, and every change due to a variation in the damping of either circuit or in the coupling between the two circuits can be followed. This was illustrated by a series of typical photographic records. A third oscillatory circuit may be taken to represent a wave-meter, and used to plot resonance curves, from which the damping can be calculated, as is commonly done in radio-telegraphic work. Here, however, we have the great advantage of knowing the damping accurately, and thus being able to check the resonance curve results under various conditions. By altering the connections, the conditions of the quenched spark sending apparatus, as used by Max Wien, Lepel, &c., was represented. Here the primary circuit is opened at the first moment that all the energy has been transferred to the secondary circuit, and no further beats or spark-gap losses occur. Results were given showing that the oscillograph can be used to find the losses in condensers at various frequencies by discharging the condensers through inductances of known resistance.—Prof. G. W. O. **Howe**: Some radio-telegraphic apparatus in use at the City and Guilds College. The wireless telegraphic receiving apparatus was shown connected up to the aërial, which is 260 feet high. A transformer specially designed for experimental work at long wave-lengths was shown. By means of a Brown telephone relay and special trumpets fitted to the telephone receiver, the time signals and messages sent out from Norddeich and from the Eiffel Tower can be plainly heard anywhere in the lecture theatre. The various types of receiving apparatus in use at the college were shown.

Zoological Society, April 4.—Dr. Henry Woodward, F.R.S., vice-president, in the chair.—Dr. H. B. **Fantham** and Dr. Annie **Porter**: Diseased bees and combs infected with a minute pathogenic protozoal parasite, apparently the same as *Nosema apis* found by Zander and Doflein in diseased bees in Bavaria. Microscopic preparations and drawings of the parasite, *N. apis*, were also shown, as

well as healthy bees and combs in contrast. The material was obtained from Cambridgeshire and Hertfordshire in March. The infected combs were brown in colour instead of the normal yellow, while the infected bees suffered from a sort of dry dysentery, which rapidly proved fatal. The pathogenic agent of this dry dystentery, *N. apis*, formed thousands of minute spores, which fouled the hive, while infection was probably spread to new hives by hungry, weakly bees attempting to enter healthy hives. The spores, about 2 to 3 μ by 4 to 6 μ, were the resistant and cross-infective stages of the protozoon. The parasite N. *apis* was closely allied to that of pébrine, the silkworm disease due to *N. bombycis*. The trophozoite and pansporoblast stages of *N. apis* had been observed, as well as some spores with polar filaments extruded. Like N. *bombycis*, the bee-parasite was possibly capable of hereditary infection, as infected bee-larvæ had been found. The only certain destructive agent of the microsporidian spores was fire, and all infected bees and hives, and any débris therefrom, should be most carefully burned. In the opinion of the exhibitors, the microsporidian parasite N. *apis* had been responsible for much of the bee-disease recorded in this country since 1906, especially in 1906, 1907, and 1911. The exhibitors first noticed the parasite in 1906 in diseased bees obtained from the Isle of Wight; its full significance was grasped in 1907, but owing to the difficulty of obtaining material the exhibitors' results were not published. As much attention was now being directed to "bee-disease," the exhibitors briefly recorded their observations. It was not asserted that microsporidiosis was the only disease of bees current in Great Britain at present, as Dr. Malden had investigated a bacillary infection in bees. Microsporidiosis had probably been introduced from the Continent into British apiaries.—Dr. R. T. **Leiper**: Nematode parasites obtained from animals in the Zoological Gardens during the year ending November, 1910. The collection contained a number of new forms, of which a systematic account will be published later. Among the more interesting of the known forms were *Rictularia plagiostoma* from a palm-civet, a number of species of Polydelphis from various pythons, *Dicheilomena horrida* from the South American ostrich, and *Dictyocaulus filaria* from the lungs of sheep. From the observations it appeared that the change of food and general conditions obtaining in the gardens were unfavourable to the continued existence of the intestinal parasites an animal may harbour on its admission. The number of cases of auto- and re-infection during captivity was strikingly small, and bore testimony to the cleanly surroundings in which the animals were kept. In four cases only was there evidence of the occurrence of accumulative infection in the gardens:—(1) a number of giant toads died from lung infection with *Rhabdias bufonis*; (2) the wolves appeared to be heavily infected with *Ascaris canis*; (3) a sheep died from pneumonic condition resulting from an intense infection with *Dictyocaulus filaria*; (4) the tortoises had oxyuriasis. In all these cases repeated infection undoubtedly had followed from contamination of food and drink with fæces containing eggs of the parasite. The infection could be eliminated by steam sterilisation of the cages, or still more easily by changing the species of animal living in the particular paddocks or cages, for helminthes were often peculiarly selective as regards their hosts, and those flourishing in one animal sometimes found it impossible to continue their life even in closely allied forms.—F. E. **Beddard**: Some mammalian tapeworms collected from animals which had died in the society's gardens. This collection was the result of nearly two years' examination of a very large number of animals, but did not contain a very large number of species. Tapeworms were by no means so common as other parasitic worms, particularly nematodes, which were the most abundant among the animals in the gardens.—. A. **Mörch**: The natural history of whalebone whales. The paper directed attention to, and threw light upon, some of the problems connected with the migrations of the larger Cetacea.

Linnean Society, April 6.—Dr. D. H. Scott, F.R.S., President, in the chair.—Miss Sarah M. **Baker**: The brown seaweeds of the salt-marsh.—Conjoint communication on the genus Salicornia. (1) Dr. C. E. **Moss**: A history of the genus from Linnæus, "Species Plantarum," ed. 1, 1753, to the present time; (2) E. G. **Salisbury**: An exposition of the characters of the species comprised in the genus; (3) Dr. Ethel **de Fraine**: The anatomy of certain species in the genus.

Paris.

Academy of Sciences, April 3.—M. Armand Gautier in the chair.—F. **Henneguy**: Experimental parthenogenesis in the Amphibia. The eggs of the frog (*Rana fusca*) were caused to develop parthenogenetically by simple puncture, following the method suggested by M. Bataillon. Comparison batches of eggs were impregnated in the ordinary way. Out of a large number of the punctured eggs, four only became normal tadpoles, and these were smaller than the tadpoles from the comparison batch.—**Albert I., Prince of Monaco**: The twelfth campaign of *Princesse Alice II.*—Sir J. J. Thomson was elected a correspondant for the section of physics in the place of H. Lorentz, elected foreign associate.—Th. **De Donder**: Jacobi's multiplier.—M. **Devaux-Charbonnel**: The direct measurement of diminution of loudness, and of the characteristic of telephone lines.—Victor **Henri** and Samuel **Lifchitz**: The kinematographical study of the displacements of ultra-microscopic particles produced by very rapid sound shocks. The action was shown to be a mechanical one, and to be independent of the electrical charge on the particles.—Paul **Lebeau**: The formula of uranium carbide. Analyses of some ingots of uranium containing carbon showed a percentage of the latter higher than would correspond with the Ur_2C_3 of Moissan. Castings were then prepared containing various proportions of uranium and carbon. Metallographic examination proved all of these to consist of a single carbide with varying amounts of graphite. It was found necessary to considerably modify the analytical method used by Moissan in the analyses of these compounds, and the true formula of the carbide was found to be UrC_2.—M. **Driot**: Mercury oxychlorides. Four oxychlorides, $HgCl_2.3HgO$, $HgCl_2.2HgO$, $HgCl_2.HgO$, and $2HgCl_2.HgO$, have been isolated, and each of these exists in one form only.—E. E. **Blaise** and L. **Picard**: The mode of formation of ethyl chloroethoxyacetate; the use of this ester in the synthesis of the α-acid alcohols. An attempt to prepare the chloride $(C_2H_5.O)_2CH.CO.Cl$ failed, a molecular transposition taking place, and the compound $C_2H_5.O.CHCl.CO_2C_2H_5$ being produced.—P. **Lemoult**: The new series of leuco-bases and colouring matters derived from diphenylethylene.—G. **André**: The conservation of the salt material in an annual plant: distribution of the fixed elements.—P. A. **Dangeard**: The conditions of chlorophyll assimilation in the Cyanophyceæ.—Jean **Bonnet**: Nuclear fusions without sexual character.—M. **Vermorel** and E. **Dantony**: The increase in the moistening power of anticryptogamic solutions for spraying.—E. **Kayser**: Researches on the juice of beer yeast.—L. **Bordas**: The intestinal cæcum and the rectal glands of the Lepidoptera.—P. **Chaussé**: Experimental tuberculosis in the dog. Under normal conditions, the latent mesenteric tuberculosis experimentally produced in the dog completely disappears from the system in 200 days.—L. **Cayeux**: The marine deposits resting on the middle Miocene in Crete.—Alphonse **Bergot**: The exact determination of the salinity of sea water by the measurement of the index of refraction. The refractometer was modified to read the index to 0·00001, and the relation between refractive index and concentration of salt was shown experimentally to be linear.

Cape Town.

Royal Society of South Africa, March 15.—Dr. H. H. W. Pearson, vice-president, in the chair.—Dr. Thos. **Muir**: Sylvester's and other unisignants. Unisignant is the name given to a peculiar class of multilinear functions which though expressible as determinants are quite unlike the latter functions in their properties, having, for example, in their final development nothing but positive terms. Probably the first instance of such a function was observed by Sylvester. The object of the present paper is to throw fresh light on Sylvester's work by bringing it into the same field of view with certain recent investigations of a mere

general character about to appear in *The Quarterly Journal of Mathematics*.—R. T. A. **Innes**: Upon the fourth order perturbations in the motions of Satellites III. and IV. of Jupiter. The author recomputes and practically confirms the values of certain long-period inequalities in the longitude of the third great satellite of Jupiter originally discovered by the late M. de Haerdtl. These inequalities are due to the near approach of commensurability of the mean motions of the III. and IV. satellites; seven times the mean motion of IV. being nearly equal to three times that of III, so that although these inequalities depend on the 4th powers of the eccentricities they exceed the limit of II. adopted in Prof. Sampson's "New Tables of the Great Satellites of Jupiter, 1910." The inequalities in the motion of IV. are now computed for the first time. In the sum these inequalities will at times amount to about 8" in the longitude of III. and 10" in that of IV.—C. L. **Biden**: The funeral ceremonies of the Hottentots. The Hottentots have their medical men who treat patients during illness. Like most South African tribes, witchcraft is practised by these medicine men, and the sick are told that their enemies, bad relatives, and bad neighbours are the cause of illness. In the event of death following, the medicine man attributes the disaster to the bad influence of certain parties, actually naming the persons he thinks concerned. Formerly these responsible persons were put to death; now it leads to much hatred and personal feeling among the Hottentots. Immediately after death they prepare for the funeral. A grave is dug by means of a gemsbok horn and a roughly made wooden shovel. The ceremonial is then described. After the funeral a dance is held, and festivities are indulged in all through the night. For a few weeks the male relatives of the deceased go to the grave every morning before sunrise, quite naked, and pray to the "taas" (ghost). After that time they suppose that the ghost has left the grave and has entered an animal called by them "thas" jackal. This animal they assert has never been caught, and it can only be killed by a silver bullet.—Prof. W. A. D. **Rudge**: The meteorites in the Bloemfontein Museum. The paper contains an account of the meteorites in the Bloemfontein Museum. There are two fragments of the Kroonstadt fall of 1877. These apparently consist of a tough fibrous mass of iron-nickel alloy, with an aggregation round it of fine particles of silica (asmanite?) troilite pyrites, and apparently felspar. The larger meteorite which fell at Winburg, 1881, contains 94 per cent. of iron and 2 per cent. of nickel. The nickel is confined to a few veins which run through the mass of the meteorite. From these veins crystals of the alloy can be separated by dilute sulphuric acid in which the alloy is insoluble. These crystals seem to be skeleton forms built up of triangular plates, the interstices being filled up with amorphous carbon. The iron is very soft, but patches of hardness occur. The "Widmanstatten" lines are not so well developed as in most iron meteorites, probably due to the nickel being located in veins instead of disseminated throughout the whole mass. The weight of this meteorite was about 50 kilogrammes, and it is markedly magnetic, having a number of poles. The alloy of nickel and iron retains its susceptibility up to a dull red heat.—J. R. **Sutton**: Seismographic record of the South African earthquake of October, 1910. The extent of the movement of the horizontal pendulum during the quake was about one-half its average daily E.W. oscillation.—James **Moir**: (1) Colloidal gold and purple of Cassius. Description of behaviour of chloroauric acid dissolved in 200,000 parts of water towards a number of reducing agents. The coloration produced by pure stannous chloride $SnCl_2$ is not purple of Cassius, but a brown of remarkable stability, which the author shows is not due to extreme fineness of division, and which may be colloidal aurous chloride. Purple of Cassius results when $SnCl_2$ and an oxidant with loosely bound oxygen are employed. The tin in the purple is shown to be merely a vehicle for finely divided gold, the shade varying from pink to indigo according to the rapidity of formation, the first division being obtained by the slow reducing action of glycerol. (2) Some remarkable oxidation products of benzidene. An investigation of the beautiful blue products obtained from benzidene by certain processes of oxidation, such as the blood-test. The products obtained by the action of chromic acid and of ferricyanide are shown to be the chromate and ferricyanide respectively of diphenoquinone-diamine $NH:C_6H_4:C_6H_4:NH$, but the latter is an extremely reactive substance and polymerises easily to very insoluble substances of the aminoazo-dye class. Benzidine is the sole reduction-product of the blue substances as freshly prepared. The violet azo-dye appears to be $NH_2.C_{12}H_8.N:N.C_{12}H_8.NH_2$.—H. W. **Tarbutt**: The Egyptian influence on Rhodesia ruin builders, or *vice versa*. The object of this note is to show that MacIver's statement that the Rhodesian ruins are of native origin does not seem too improbable, if the articles found in or about the Rhodesian ruins are compared with similar articles of Egyptian primitive art. The author contends that the very resemblance between them is not confined to one or two articles, but to almost everything that has been found, and illustrations comparing the Rhodesian and Egyptian objects are given to support the theory.

DIARY OF SOCIETIES.

WEDNESDAY, April 19.

Royal Meteorological Society, at 7.30.—Variations in the English Climate during the 30 years, 1881–1910: W. Marriott.—(1) The Value of the Two-theodolite Method for determining Vertical Air-motion. (2) An Automatic Valve for Pilot Balloons: Captain C. H. Ley.

ENGINEERING ARTICLES IN THE ENCYCLOPÆDIA BRITANNICA.

Collection of Articles (loose sheets) dealing with Engineering, from the New (11th) Edition of the Encyclopaedia Britannica. (Cambridge: University Press, n.d.)

THE articles dealing with engineering subjects, in that portion of the new edition of the "Encyclopædia Britannica" which ranges from aëronautics up to irrigation, have been issued separately for the purposes of review. As a whole, the articles attain a high standard of excellence, and the writers are men of acknowledged authority. Some of these articles have appeared in previous editions, and are substantially reproduced; but they have been brought up to date in most cases. Many new subjects have been dealt with in an interesting manner, and the appended bibliographical references are generally of considerable value, and will guide in their choice of authorities readers who desire to obtain fuller information. As might be expected from the necessity for extra condensation existing in encyclopædic articles, there is a lack of due proportion on the part of some authors in treating individual branches of particular subjects.

The article on aëronautics has special interest at the present time, and deals fully with aërostation—the construction and behaviour of machines which are lighter than air. Aviation—the branch of aëronautics which is devoted to flying machines heavier than air, is treated very briefly under the heading of aëronautics, but is also discussed under "Flight and Flying." This subdivision is arbitrary, and from the engineering side it would be more convenient had flying machines of all kinds been grouped together.

The article on "Aqueducts" contains a comparatively brief account of modern practice, but ancient works and historical facts have been dealt with in considerable detail. It is notable also that while works connected with the water supply of Manchester and Liverpool are described at length, no reference is made to the later and equally important works carried out for Birmingham. The article on "Docks" is of great interest and value, giving good information as to most works of the kind; but it is strange to find only the briefest descriptions of modern floating dry-docks, although, as is well known, their development in recent years has been remarkable. Formerly graving docks were practically supreme; they have now become relatively less important, especially in foreign ports, where floating docks are to be found which are capable of lifting the largest ships.

Under the heading of "Canals" one would have expected to find fuller reference to the facts disclosed and suggestions made in connection with the recent inquiry by a Royal Commission into the present condition and use of British canals. The actual reference occupies only about a dozen lines, and looks like an afterthought. A few of the most important canal works of modern times are dealt with in separate articles, including the works at Panama and those incidental to the great enlargement of the Kiel-Brunsbuttel Canal, now being carried out by Germany, as a part of her naval strategy rather than with a view to any commercial benefits to her mercantile marine. In the treatment of certain subjects considerable latitude appears to have been permitted to writers, although the relative importance of these subjects hardly justifies the prominence given to them. In other cases there has been a degree of compression which is to be regretted. Editorial control of such technical matters is undoubtedly difficult, but it might in many cases have been exercised with advantage. The article on "Concrete," for example, deals with a subject of enormous and increasing importance, especially at a time when "ferro-concrete" construction—termed by the writer "steel-concrete"—is making rapid strides, yet its discussion—excellent so far as it goes—is compressed into five pages. On the other hand, the discussion of "Fire and Fire Extinction" occupies more than three times as much space. The latter subject is undoubtedly important, but from an engineering point of view it has not the relative importance which mere space measurement would suggest.

Apart from these criticisms on a few points of detail, it is a pleasure to record the opinion that on the whole the engineering articles constitute a valuable epitome of recent professional practice, and will be of great value for purposes of reference. Not a few of them are worthy of separate publication, the treatment displaying both thoroughness and ability. Some attain almost to the dignity of standard treatises on the subjects discussed, and amongst these may be mentioned the contributions of Dr. Unwin on "Bridges and Hydraulics," Mr. Dugald Clerk's article on "Gas Engines," Prof. Ewing's on "Air Engines," and Mr. Milton's on "Boilers." In many other articles modern practice is well described, and new departments of engineering are illustrated.

Special interest attaches to the articles on "Conveyors," "Elevators," and "Destructors," which deal with engineering appliances that are essential to the life and work of great centres of population. The paper dealing with "Divers and Diving apparatus" is admirable in its clearness and completeness, containing descriptions of recent improvements for working at great depths below the surface of the sea. Dredging is another subject which has been treated at length, and with great ability, both in relation to the construction and maintenance of channels and harbours, and its applications for purposes of scientific research. Diamond and gold mining are dealt with by high authorities in a manner which the general reader can understand. Coal and coal mining are equally well handled. A large number of shorter and less important articles are devoted to descriptions of engineering details and processes. Irrigation receives the attention it so well deserves, excellent accounts being given of the great and beneficial results obtained by British engineers in India, Egypt, and elsewhere, as well as the work done by foreign engineers in other countries.

A few short biographies are included in the

engineering section of the "Encyclopædia," although there is no clear indication of the principle on which the subjects have been selected. The biography of Sir Benjamin Baker is hardly worthy of the man. The article is very brief, and it gives no adequate idea of the great engineering works for which Baker was responsible. This is much to be regretted. On the other hand, the notices of Bessemer and Brassey (father of Lord Brassey) contain excellent summaries of widely differing careers. The description of the "swinging saloon" devised by Bessemer for cross-Channel steamers, and of the failure of that system in practice, illustrate the dangers attaching to ventures into new regions even when they are made by capable inventors who have achieved success in other directions. Bessemer had not mastered the principles of the behaviour of ships at sea, otherwise he would not have attempted to keep a swinging saloon level as the steamer rolled by the control of an attendant who watched the indications of a spirit-level, and manipulated hydraulic machinery. Thomas Brassey was not an engineer, but was simply one of the first and greatest contractors for engineering works. He is shown to have been a man of great business and administrative capacity. The sketch of his life brings into relief his high personal qualities and illustrates the fact that he "was one of the first to aim at improving the relations between engineers and contractors, by setting himself against the corrupt practices which were then common."

W. H. W.

EXPERIMENTAL ZOOLOGY.

Experimental-Zoologie. 3: *Phylogenese.* By Dr. H. Przibram. Pp. viii+315+xxiv. plates. (Leipzig und Wien: F. Deuticke, 1910.) Price 18 marks.

THIS volume, the third instalment of the author's work on experimental zoology, is planned on the same lines as the preceding parts; it deals essentially with the nature of species and the origin and modification of specific characters. It gives a concise summary of the work which has been done in various branches of the subject, with short discussions and criticisms where the author considers them necessary. It is on the whole, however, rather an encyclopædia of the phenomena of species than a discussion, as is indicated by the fact that 70 out of 315 pages are devoted to the bibliography and index. In some cases rather more criticism would have been welcome, for the author summarises papers of very different importance with an impartiality which sometimes makes it difficult to gauge the relative value of the work.

In general, the treatment is exceedingly complete, and includes accounts of papers which might have been overlooked without giving just cause for complaint, but there are a few rather surprising omissions. For example, in dealing with heredity, the work of the biometrician school is scarcely mentioned apart from Galton's formulation of the law of ancestral inheritance; Nettleship's Bowman lecture on hereditary eye-diseases is omitted; and still more surprising is the absence of any reference to Gamble and Keeble's work on the effects of coloured surroundings on pigment development. Poulton's work on the same subject is also treated rather inadequately.

The plates are of the semi-diagrammatic kind used in the first volume, and are excellent as illustrations of the text; they are folded so that a plate can be turned out for reference while reading, but it would make it easier to find the plate required if the numbers were visible when they are folded. As in the previous volumes, the use of the letters *a* and *α* is sometimes confusing; in plate vii. we notice that the numbers 4*a* and 4*c* are interchanged, and in the description of plate xxiv., Fig. 14, the use of the word "heterozygote" is misleading. We mention these small defects in the hope that an English translation will be undertaken, in which they may be remedied.

The book opens with a discussion of the criteria of species, in which the importance of physiological characters (blood tests, &c.) is emphasised, and a tabular summary is given of various classes of specific characters. The two short chapters which follow deal with the possibilities of asexual (somatic) and sexual transmission of characters. Chapter iv. consists of a very complete catalogue of experiments in hybridisation, both of crosses between distinct species and between races or varieties. This fills 100 pages, and is most valuable as a list of all the most important cases up to the year 1909. In the succeeding chapter these results are analysed. It is concluded that the first cross (F_1) may show (1) a blend, (2) a mosaic, or (3) alternative appearance of the parental characters. In the F_2 generation the first and second classes may give young all like F_1, or Mendelian segregation may occur; the third class always gives a Mendelian result. The view that Mendelian characters are borne by chromosomes is provisionally accepted. A good account is given of dihybrid and polyhybrid cases, and of the phenomena of "latency" and sex-limited inheritance. In crosses between distinct species the characters often blend, because apparently corresponding characters in different species are not allelomorphic. The relation of Mendel's and Galton's laws to each other is described, and in a discussion of the relation of alternative to blended inheritance a suggestion is made for bringing both into one category.

Chapter vi. (63 pages) gives a summary of work in the production of characters by environment, and their inheritance. Among the work on Protozoa, Dallinger's experiments are not mentioned; and in the long section devoted to the Lepidoptera, we think that a fuller discussion might have been given of the means by which colour-production is influenced by temperature and other factors, as indicated, for example, by Gräfin von Linden's work. The theoretical conclusions to be drawn from this chapter are postponed to the end of the book. In the chapters on selection and mimicry, a good account is given of experiments and observations by various workers, and it is concluded that although natural selection can bring about the survival of the fittest, and although mimicry of a noxious species may be a protection to the mimic, yet selection can originate nothing, but only isolate "pure lines" already existing.

In the final chapter causes of change in specific characters are classified (chemical, mechanical, light, heat, &c.), and finally a valuable discussion is given of the three chief hypotheses of specific change—germinal variation, transmission of somatic acquirements, and parallel effects of environment on soma and germ. The arguments for and against each are set forth in tabular form, and it is concluded that few, if any, observed facts are inconsistent with the third hypothesis, while it has important experimental and circumstantial evidence in its favour.

L. D.

REFERENCE BOOKS OF BIOCHEMISTRY.

Biochemisches Handlexikon. Herausgegeben von Prof. Emil Abderhalden.

iv. Band, 1 Hälfte: *Proteine der Pflanzenwelt, Proteine der Tierwelt, Peptone und Kyrine, Oxydative Abbanprodukte der Proteine, Polypeptide.* Pp. 352. Price 14 marks.

vii. Band, 1 Hälfte: *Gerbstoffe, Flechtenstoffe, Saponine, Bitterstoffe, Terpene.* Pp. 538. Price 22 marks.

(Berlin: J. Springer, 1910.)

THESE two books form the first halves of vols. iv. and vii. of a work in seven volumes on biochemistry, which is intended, as the editor states in the preface, to perform the same function for the biochemist as "Beilstein" does for the organic chemist.

Although the work is termed a hand-lexicon, the articles are arranged as monographs, and there is no discoverable system by which the reader may trace out any detail to which he may want to refer in any one of these long articles. There is no table of contents nor any index to help one, and in any well-regulated laboratory one might almost as well, so far as trouble is concerned, search out the original literature as refer to one of these articles.

For example, one of the best articles in the two half-volumes under review is that on the saponins by Prof. Kobert, of Rostock, occupying 84 pp., and describing nearly as many members of the group as there are pages in the article. There is no apparent method in the arrangement of the description of the members, and nothing to guide us as to where any particular member is to be found. It so happens that the writer is at present working at the biochemistry of an important and well-known saponin occurring in ivy-leaves, and therefore he looked keenly through these 84 pp. to see if there was anything new about it. The search was disappointing; after a long and weary hunt not one word was to be found in the whole article concerning it. This will never do in a work intended to be the biochemical rival of "Beilstein." In that work each volume carries its index, and it is to be hoped that purchasers of the present work will not have to wait longer than the appearance of the second halves of the volumes for the indispensable index.

The two half-volumes which have so far appeared form very dull, dry, and uninteresting reading even for a "Handlexikon," and lack the saving virtues of a lexicon of completeness and ready accessibility to detail.

It would have been an improvement if the articles had been issued as separate monographs; and even then one might question why it was necessary to write some of them at all. Better monographs and more complete have been compiled by other writers in several of the subjects, and are well known and accessible to all workers in biochemistry; and in certain of the others the subject of the monograph is interesting to such a small circle of readers only that it might still be allowed to rest in the original archives, where the half-dozen workers on the subject know quite well where to find the papers they require.

One wonders how many readers will take any deep interest in the wonderfully detailed article of 112 pp. from the pen of Dr. O. Hesse on "Die Flechtenstoffe," under which title, the author informs us at the outset, we are to understand "organic compounds which occur only in the 'Flechten' or lichens, and accordingly are peculiar to these plants." Again, of the very few who have the requisite special training to struggle through Dr. Hesse's article, how many will ever require in the entire course of their lifetime any of the wondrous detail of Dr. Kobert's article on saponins coming immediately after it? There is certainly a deep and abiding comfort in thinking upon the amount of human lore in complete ignorance of which one can pass happily and successfully through this mortal life.

Turning to the articles in the two half-volumes which interest a wider circle of readers, such as those in vol. iv., first part, on the vegetable and animal proteins, their hydrolytic and oxidative products, and the polypeptides, these may be described as somewhat more useful, although the cast-iron form into which they are thrown robs them of much of their interest. One becomes somewhat fatigued by the continuous repetition in mournful, broad-faced type of Vorkommen, Darstellung, Bestimmung, Koagulationstemperatur, physikalische und chemische Eigenschaften, physiologische Eigenschaften, u.s.w. If the monograph form is to be selected for a hand-lexicon, why not give some freedom to the authors to throw the matter into their own form and style, and so infuse some life into what they are writing, instead of dissecting it out in this way like a dead body? An index to each monograph would easily give orientation to anyone looking for a special detail. The cast-iron plan pursued in the present work, moreover, loses space instead of gaining it by continued reiteration of the same facts for each member of a many-membered class. For example, the actions of the digestive juices upon polypeptides could be given in tabular form in a space of one or two pages by putting the whole thing connectedly and together; instead of this, practically the same statements are repeated in describing each member of the legion of polypeptides. Again, in the article on the saponins, the reaction of each individual to the generic colour-test with concentrated sulphuric acid is given with tiresome repetition, as well as many other matters of

a general character, all of which, it may be remarked, have in this article already been given in an introductory description of general properties of the group.

Apart from details, nearly all the articles which deal with subjects of general interest will be found to present a well-known and familiar appearance to the biochemist. Any laboratory which possesses E. Fischer's work on the amino-acids and polypeptides can have little service for the present monograph on the same subject in this series. The article on the vegetable proteins in the "Biochemischen Arbeitsmethoden," written by the same author, edited by the same editor, and issued by the same publishing house (reviewed in NATURE a few months ago), takes much of the wind out of the sails of the article on the "Proteine der Pflanzenwelt" in the present colossal work, which is appearing simultaneously with the equally colossal "Handbuch der biochemischen Arbeitsmethoden" under Prof. Emil Abderhalden's guidance.

There would appear to be a paying market for any large work on chemistry issued in Germany, for that country seems to have become the world's factory for this type of literature, and of all German editors Prof. Emil Abderhalden seems to be the most prolific, as witness the twin works, each of about seven volumes, and each volume so fat that it becomes itself a twin, issuing at the same time under his editorship. But one occasionally feels there can be too much of this thing, and is inclined to cry out, "Halt, halt; we must work as well as read," and spend our money, at least in part, upon materials and equipment for our laboratories, which bid fair to be starved by too much cooking for our libraries.

BENJAMIN MOORE.

METABOLISM OF PLANTS.

Der Stoffwechsel der Pflanzen. By Prof. A. Nathansohn. Pp. viii+472. (Leipzig: Quelle and Meyer, 1910.) Price 12 marks.

THE great advances that have been made in recent years in research into the leading principles and fundamental facts of the physiology of plants have made it necessary to specialise in particular directions, and the literature of the subject shows in consequence a tendency to deal with two aspects of the general life of plants almost entirely apart from one another. Of these the first embraces the phenomena of the individual life; the second, the relations of the individual to the conditions of its environment. In the present volume Dr. Nathansohn has undertaken to deal almost exclusively with the former of these problems, and has set before himself the task of discussing the present position of the metabolic phenomena characteristic of the green plant. The book is not intended to displace the standard text-books on the subject, but to deal more exhaustively than is possible in the latter with the gradual unfolding of knowledge and the gathering together of the mass of detail which has been accumulating for the past decade or longer.

In pursuance of this design he has dealt with his subject in eight sections, following the general line of treatment of his predecessors. Beginning with the absorption of material from the soil and the atmosphere, he deals with the construction and management of foods, certain problems of nutrition, immediate and deferred, respiration and the regulation of energy, and the phenomena of secretion and excretion.

The discussion of the first of these questions, involving the absorption and transport of water, involves the examination of many physical and chemical questions, which are ably handled, with a due avoidance of dogmatism. The author introduces the second problem with a historical summary of the earlier work on the question of photosynthesis, or, as he prefers to call it, carbon dioxide assimilation. It is a little disappointing to find him almost stopping short here with the researches of the Sachsian period, and dealing very briefly with the result of later investigations. His treatment of the metabolic processes and phenomena in which non-nitrogenous substances are concerned leads one to regret that while the sugars are dealt with at great length, he has very little to say about the glucosides, inulin, and the celluloses. The metabolic phenomena in which these are concerned are of considerable importance, and a graphic presentation of them is just now much to be desired. In his treatment of nitrogenous substances, too, Dr. Nathansohn has dealt at some length with the proteins, giving them, as is natural, a position commensurate with their importance in metabolism; but he leaves us wishing he had devoted more space to such bodies as the alkaloids, which he dismisses somewhat briefly.

While appreciating the great amount of valuable material which the book contains, the English reader will be struck with particular deficiencies. The point of view leaves something to be desired. The book treats of the plant as a machine rather than as a living organism. No doubt it is a machine, but it is much more than that; it is capable of regulating all its chemical and physical processes according to its requirements from time to time and to the variation of external conditions. The part played by the living substance in the various changes and rearrangements that constitute metabolism is only too easily lost sight of. It is especially necessary to emphasise this fact, particularly in the discussion of the respiratory phenomena, or one might suppose that the respiratory interchanges take place for the most part without any involvement of the protoplasm, as if sugars, or fats, or what not, are oxidised in the cell by direct action of oxygen upon them. The fact that respiration is an indication of profound auto-decomposition and reconstruction of the protoplasmic molecule might have been made more impressive to the reader of the chapters which deal with this subject.

Another feature which is very remarkable is the narrow range of literature which the author quotes. Out of a total of some 450 references, a bare dozen or so are English, and scarcely more than a score are French. The English reader will certainly regret the very scant attention that has been paid to Eng-

lish researches. Surely in the story of the metabolism of the carbohydrates room might have been found for the classic work of Brown and Morris, and Brown and Escombe on the physiology of the foliage leaf and of the germinating barley grain; in other places for the work of the Cambridge school on the enzymes, the phenomena of gaseous interchange, and the conditions of respiration; and for the researches of Chittenden, Vines, and others on the phenomena of proteolysis. The discovery of erepsin is not mentioned, though its importance in the metabolic phenomena of proteins is beyond dispute. The author is apparently satisfied with the researches of the German scientific world, which, from the point of view of the advancement of knowledge, can only be regretted.

J. R. G.

AGRICULTURAL ESSAYS.

Lectures Agricoles. By Prof. C. Seltensperger. Pp. 576. (Paris: J.-B. Baillière et Fils, 1911.) Price 5 francs.

"IL y a trois manières d'enseigner: on peut instruire en amusant, instruire en ennuyant, et même ennuyer sans instruire." The book before us opens with this incontestable statement, and when we reach the end we feel that the editor has kept well clear both of the second and third methods, and has succeeded in maintaining interest throughout.

The plan of the book is, we believe, entirely new in agriculture. It is not a text-book in the ordinary sense of the word. There is a scheme running through it, but the chapters are not written by one author, or even written expressly for the book, but are taken from the writings of the best known French agriculturists. Thus there is a lack of continuity and an absence of detail, but by way of compensation the reader gets a fine breadth of view, and he is introduced to the best agricultural experts in his country.

M. Schloesing writes on the soil, and succeeds in a very few pages in giving a picture that will carry the student a long way in his studies. M. Nivoit writes on railways and agriculture; he points out that France is not specially rich in minerals, but she has a good soil and an incomparable geographical position; thus a great variety of crops is possible, and good transport facilities become indispensable. Instances are given of what has already been accomplished: the Compagnie Paris-Lyon-Méditerranée carries fruit from Avignon to Paris in 24 hours, to London in 40 hours, to Hamburg and Berlin in 80 hours. The advantage to the grower is enormous, but the local consumer may suffer; where formerly he could often buy fruit at very low prices, he may now have to pay actually more than in some of the markets further off. This, however, is a detail that is easily remedied.

The applications of electricity in agriculture are dealt with by M. Petit. It is regarded only as a source of power, the direct effects of the discharge on plant-growth not being considered. As a driving power it has many advantages, and it is attracting attention in France; for us here, unfortunately, it is as yet inaccessible in country districts.

A number of chapters deal with the general economic and social problems of agriculture. Where there are so many small holdings and so few hedges as in France, the question of boundary lines between one man's property and his neighbours' becomes a fruitful source of dispute and of vexatious litigation. M. Muret deals with this problem, and gives some very useful advice to the disputants.

There are a number of admirable illustrations throughout the volume, which, however, are not always connected with the text, and are sometimes not even explained. In several chapters, especially those dealing with insect and fungoid pests, the absence of detail is felt more than it is elsewhere. References are, however, always given to inexpensive text-books where the further information can be obtained. Considering the very wide range covered—practically the whole of the agriculture of France—and the very modest price of the book, it must be put down as one of the most generally useful of the admirable series to which it belongs.

MICROSCOPY FOR ZOOLOGISTS AND ANATOMISTS.

Grundzüge der mikroskopischen Technik für Zoologen und Anatomen. By A. B. Lee and P. Mayer. Vierte Auflage. Pp. vii+515. (Berlin: R. Friedlander and Son, 1910.)

IN this the fourth edition of an established publication the authors have not found it necessary to make any material alteration in the contents of the previous edition. They have added, however, much new substance derived mainly from various microscopical journals; medical periodicals, numerous though they be, having, to the authors' regret, been almost entirely unproductive. As will be gathered from the title the scope of the work is limited to anatomical and zoological microscopy. Such limitation is strictly observed. Even in the general paragraphs all temptation to wander off into by-paths is sternly resisted. Although the authors give freely of their own experience, they refer largely to the labours of others. The book is, in fact, crowded with condensed information, which has been industriously and exhaustively compiled during the last four years from suitable sources in many languages. References to these sources are always given. Nine chapters (131 pages) are devoted to the preliminary operations of killing, fixing, hardening, and imbedding. Seven chapters (94 pages) deal with staining; five (45 pages) with cements, varnishes, injections, and bleaching. Nine (140 pages) of the remaining ten chapters treat minutely the specific examination of the embryo and of various tissues and organs: one chapter (39 pages) is restricted to invertebrates. There is a copious index of no less than sixty-two pages, so that consultation of the contents is easily made.

A glance at any chapter, or group of chapters, readily reveals the thoroughness of compilation and the judgment of the authors. Thus, the essential process of imbedding is introduced by a general chapter (No. 6) on the subject. This chapter (*inter alia*) summarises the merits and demerits of the chief varieties of microtomes. It also summarises the ad-

vantages and disadvantages of paraffin and celloidin as imbedding materials. Around these much controversy has raged. The authors conclude that, while very thin sections can without doubt be best obtained in celloidin, the greater difficulty of manipulation and the greater requisite dexterity will probably lead an inquirer who wishes to work out a structure quickly and easily to adopt paraffin. As paraffin and celloidin are the chief imbedding agents, each of these is fully treated in a separate chapter, each chapter being of about twenty pages.

The chapters on stains are particularly full, and every colouring medium appears to be included. The recipes for their composition are given with quantitative accuracy, and, in the general preface, Dr. Mayer raises a protest against the vagueness with which such concoctions are frequently quoted. In several cases the important matter of stain durability is suitably discussed. The synonyms of tar dyes are always given.

It may be that to many investigators the most useful chapters will be those which deal specifically with organs and tissues, while other students will perhaps find the chapters on invertebrates the most attractive. Fulness of treatment is as much in evidence in these specialised regions of applied microscopy as in the more general parts of the book. The chapter on embryology (33 pages), for example, covers the animal kingdom; nerves are treated in three chapters (54 pages); and, under the heading of Echinoderms, each of the main subgroups is separately described.

The work as a whole gives the impression of unvarying thoroughness and completeness. It should be a valuable and indispensable auxiliary in the library of every biological laboratory. An appendix, compiled while the book was in the press, brings the contents thoroughly up to date. A. N. D.

DARWINISM AND PHILOSOPHY.

Dogmatism and Evolution: Studies in Modern Philosophy. By Prof. T. de Laguna and Dr. Grace A. de Laguna. Pp. v+259. (New York: The Macmillan Co.; London: Macmillan and Co., Ltd., 1910.) Price 7*s.* 6*d.* net.

THE authors explain that the term "dogmatism" is here used to denote the body of logical assumptions which were generally made by thinkers of all schools (*e.g.* Berkeley and Hume, as well as Descartes and Leibniz) before the rise of theories of social and organic evolution. The first part of the work is devoted to the analysis and illustration of the dogmatic principles. The second part, entitled "Revolution and Reaction," deals with the opposition offered to the old dogmatism by the critical philosophy and absolute idealism. The third part, which is developed to greater length, deals with the pragmatist revolt.

From our naturalist's point of view we turn with most interest to what the authors have to say in regard to the Darwinian theory of evolution, and we are not disappointed. It is shown that while the idea of evolution first became effective in the realm of social science, it was conceived in an essentially abstract fashion, without any adequate consideration of the factors which operated. "It was not until the work of Darwin in biology that there existed anything like a scientific theory of evolution, based on wide and intensive empirical study." But "the importance of Darwin's work did not lie simply in the fact that it provided an acceptable theory of the evolution of organic species." His success gave investigators in other fields confidence in their clue, and opened the way for a universal theory of evolution. Moreover, "the bridging of the gap between man and the lower orders meant a transformation of those sciences dealing with essentially human activities."

While psychology and ethics have developed in post-Darwinian days under the application of evolutionary methods, logic has until recently remained untouched. "Until the rise of pragmatism no thoroughgoing attempt was made to explain the fundamental notions of logic itself in the light of the selection hypothesis." "Pragmatism is the first whole-hearted attempt at an appreciation of the significance of Darwinism for logical theory." What the authors seek to show is that the attempt has only half succeeded;

> "that conceptions and methods inherited from the dogmatic empiricism of the eighteenth century go far to vitiate the evolutionary empiricism of to-day; and that the critical revision of these inherited notions from an evolutionary standpoint will make of pragmatism a far less iconoclastic movement."

The student of organic evolution will be interested in the clear contrast which the authors make between the Darwinian and the Hegelian concepts of evolution. The course of organic evolution is not conceived by biologists as a dialectic; it is not to be explained in terms of mere logical relationship; external circumstances, instead of being unessential, are determining factors. The later stage cannot be described as the necessary realisation of the earlier. "Had external circumstances been ever so little different, the succeeding stages of the process might have been profoundly different." Organic evolution cannot be properly described as the progressive unfolding of a reality potentially existent throughout. Applying the point of this contrast to rational thought, the authors maintain that on the Darwinian view, thought is regarded not as the end and determinant of organic development, but as a product and (more importantly) as a moment or factor in that development—"a factor whose existence and nature are throughout conditioned by the part it has to perform in organic life." J. A. T.

GEOLOGY AND THE DOCTRINE OF DESCENT.

Abstammungstheorie mit Rücksicht auf Erdgeschichte. By Prof. H. Pohlig. Pp. 191. (Stuttgart: Gesellschaft "Neue Weltanschauung" and F. Lehmann, 1909.) Price 2 marks.

SCIENCE in England has been peculiarly fortunate in its popular exponents, especially on the biological side; the only regret is that they are so few. In Germany there is no lack in number, but it would be insincere to express unqualified admiration of the prevailing style. Most of us probably would prefer

Huxley to Haeckel, and the present work is an "Haeckelismus" without the redeeming grace of genius. It is dogmatic, and, still worse, it is dull.

The question of the origin of life is easy to the author. Scattered through infinite space and time is carbon, which in its original state forms the simplest germs of life (Zoatoms). These are so small that even under the highest magnification they are seen only as an irresolvable dust. It is they alone which are able to assimilate the carbon which has lost its life (we are not told how it loses its life). When the earth was molten the Zoatoms surrounded it like an atmosphere, like the meteorites around a heavenly body. Then, of course, come Protists, Protophytes, and Protozoa, and all is plain sailing until we reach the commencement of the Cambrian, where we, for the first time, encounter fossil remains; not, however, representing, as we might expect, the beginnings of life, but all, or almost all, the great subdivisions of the Invertebrata. This remarkable fact has taxed the ingenuity of geologists not a little; the author makes short work of it; two or three pages are devoted to describing the various kinds of rock metamorphism, one or other of which is asserted to have blotted all the pre-Cambrian fossils out of existence, except Eozoon, which is most likely a Stromatopora-like organism, saved by a strange chance from destruction.

Geologists, the author says, have spoken of a Carboniferous continent—Glossopteris land; this is "grund falsch," and contradicted by the facts (which are not cited).

The notion of pre-Tertiary glacial epochs is widely accepted by geologists, but it is "grund falsch" and "unthinkable." A deep sea before the Triassic period is also "unthinkable." No climatic zones were "possible" before the Tertiary era.

The profile of the Pithecanthropoids is still *very* ape-like, as is seen in the lowness of the forehead, the projecting jaws and retreating chin, the slope of the occiput, and the size of the face. (This statement is arrived at by piecing together Neanderthal man and Pithecanthropus.)

After all this, we are glad to be assured that the soul is immortal; it resides in the Zoatoms, and so may be dispersed, but not destroyed.

There are several references in footnotes, almost without exception to other works by the author.

OUR BOOK SHELF.

Grundlagen der Ballonführung. By Prof. R. Emden. Pp. vii+140+Taf. 3. (Leipzig and Berlin: B. G. Teubner, 1910.) Price 2.80 marks.

THIS book contains twenty-two paragraphs or chapters. It opens with a statement of the general laws governing the relations of a balloon to the air which supports it, beginning with the density of the gases employed and their lifting forces, and proceeding with the consideration of the distribution of force in the envelope.

Balloons are classified by the author as being of constant mass or constant volume (*i.e.* as having closed or open envelopes), and the behaviour of the classes in rising and falling is discussed.

The proper use of ballast is treated, and the importance of having too much ballast rather than too little is emphasised. Paragraph 18 deals with captive balloons, especially with regard to the height to which they can ascend in a wind. The diagram illustrating this point appears to be wrong, the construction employed indicating that the height in question is $L(1-\cos\alpha)$, where L is the length of the rope and α its inclination to the vertical, instead of $L\cos\alpha$ (as it should be).

The subsequent paragraphs are connected with the use of the ballonet and the relative merits of closed and open envelopes, and, finally, in paragraph 22 some remarks are made on the steering of dirigible balloons.

There does not appear to be much that is new in the book, but it has the merit of being compact, and most of the information it contains appears to be correct.

For how long frail structures such as balloons will have a place in warfare when opposed to the hardier, cheaper, and quicker flying machines is a question which will be decided in the next few years, but for so long at any rate Dr. Emden's book will be found useful.

A. MALLOCK.

Vaccine Therapy: its Theory and Practice. By Dr. R. W. Allen. Third edition. Pp. x+277. (London: H. K. Lewis, 1910.) Price 7s. 6d. net.

THE principle of treating bacterial infections by vaccines, *i.e.* sterilised preparations of the organisms which are disturbing the normal balance, has taken firm hold in modern English medicine. It has not reached its present position without a struggle, and even now it must be admitted that the proof of its usefulness depends more on the cumulative weight of personal impressions than on any rigid demonstration such as an extensive case-statistic would supply. In practice, however, an increasing body of influential opinion is in its favour, and the acceptance with which former editions of this work has been received shows that it meets a demand.

The present issue, which has been entirely re-written, aims at "enabling the general practitioner to approach with confidence a case requiring therapeutical immunisation." With this object a sketch is given of the nature of opsonins, the use and meaning of the opsonic index, and the method of preparing vaccines, while the various infections are treated at somewhat greater length with regard to their special requirements. A considerable number of individual cases is given to illustrate the selection of appropriate doses, and the results which may reasonably be expected from them in different circumstances. These include failures as well as successes, and the results of recent work in this country are summarised as fully as the scope of the work permits.

As the author himself recognises, however, accurate diagnosis is a prime essential of success, and this presupposes an acquaintance with practical bacteriology, which the general practitioner does not possess, and such a book as this can do little to supply. Some space indeed might well have been saved by omitting the altogether inadequate treatment of the method of isolating and recognising the organisms which may be found in a given case, and devoted to a more critical appreciation of the problems involved in bacterial inoculations.

Die Eiszeit und der vorgeschichtliche Mensch. By Prof. G. Steinmann. Pp. iv+96. (Leipzig: B. G. Teubner, 1910.) Price 1.25 marks.

PROF. STEINMANN, with evident pleasure, contributes this work on the Ice age to a popular series issued by the firm of Teubner. The black letter type shows the audience for which it is intended, and it will admir-

ably carry on the campaign of the German geologists for a more general understanding of the earth. After indicating that an oceanic and moderately cold climate, rather than a continentally extreme one, will provide the conditions for an Ice age, the author appeals to the scenic features of a country where glaciers have worked their way. He supports the view of the over-deepening of valleys by glaciers, and clearly points out the effects of differences of pressure in different regions of a complex ice-stream. Prof. Heim would doubtless remark that the U-form indicated in the picture of the Lauterbrunnen valley (p. 21) is obviously due to taluses; but little fault can be found with the author's account of the variety of characteristic outlines traceable in all regions that have undergone an Ice age.

The etching out of cirques primarily by frost-action, as on the margin of melting snow, rather than by the glaciers that ultimately occupy them, is surely sustainable, in spite of what is said on p. 37; but we agree with the author that the erosive power of glaciers has been very freely underrated. The study of moraines and outwashed materials is used to explain the phenomena of the North German plain, and the lost freshwater lakes of Bolivia are introduced as evidence of the universality of the Ice age. New interest is aroused by the account of pre-Glacial and Glacial man with which the book concludes. G. A. J. C.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of Nature. *No notice is taken of anonymous communications.]*

Further Experiments with the Gramophone.

In Nature of April 15 and October 21, 1909, I described various experiments with the gramophone. Since then I have made many efforts to get rid of the hissing and grating noises that detract so much from the instrument as a reproducer of musical sounds, and at last I have had an encouraging measure of success. The gramophone, as will be seen in the accompanying figure, is enclosed in a wooden cloth-lined box, and a tube passes tightly through a hole in the wall of the box from the end of the taper arm that carries the sound box of the instrument. When the sound box is tightly closed by raising and locking the front lid, as seen in the figure, the sounds of the machinery, and also the vibrations from the free side of the diaphragm of the sound box, are completely damped off. The noises, caused by the friction of the needle point on the hard disc of the record, pass, of course, along with the musical sounds, through the taper arm to the tube that escapes from the box. This tube is suitably connected with lengths of tin tubing, 1½ inch in diameter, and the sounds are thus conveyed through as many feet of tubing as may be found necessary. I have found the most efficient length of the entire tube, until it reaches the horn or resonator (the attachment of which is seen in the figure), to be, say, 54 feet. The effect of the long tube, while empty, is to increase the volume of the tones, but, of course, the noises are also intensified.

I have always been struck by the fact that the friction noises seem to be quite separate and distinct from the musical tones, either when a voice is singing with an accompaniment, or during the reproduction of an orchestral piece of music—indeed, by an effort of attention, I have so trained myself that I can hear one without hearing the other. This suggests that in the ear there is a mechanism for the detection of noises of high pitch as distinct from ordinary musical tones. It occurred to me that by causing the sounds to pass through numerous narrow channels, freely communicating with each other, the noise-sounds, presumably caused by short waves of high pitch, might be damped off by interference, while the longer waves, corresponding to musical tones, might pass through unaltered, except as regards loss of energy from friction. My purpose was attained by filling a segment of the tin tube, say, from 4 to 8 feet in length, with a mixture of hard peas and beans, corrugated by age or drying. The experiment succeeded. The friction noises were damped down, while the musical tones, although rather "dulled" in quality, that is to say they lacked brilliancy, were purer, and, to my ear, much more natural.

Other substances were tried—glass balls, marbles, small fir cones, gravel, shreds of tin—but the best effect was

Gramophone arranged to get rid of friction noises.

obtained with the peas. Brilliancy was obtained by using, as suggested and made by Mr. Ernest De la Rue (who has been much interested in these researches), zinc tubes filled with fragments of corrugated zinc, and the use of these has been protected by patent by Mr. De la Rue. By a combination of the zinc fragments with the peas and beans, I get delightful effects, so that the gramophone-music is so immensely improved that I cannot listen with any pleasure to the "naked" gramophone sounds, as the attention is not now disturbed by the "frying-pan" noises.

As listening to music so reproduced is a kind of auditory illusion, any contrivance that will heighten the illusion may be expected to give more pleasure if the illusion is of the right kind. Usually one feels a sense of unreality in the music apparently rising from the bottom of the "horn," more especially in listening to a human voice. To get rid of this, I angle the horn, as shown in the figure, so as to reflect the sound waves from a tin reflector (parabolic in character) so placed as to send the sounds to the other side of the room. One then ceases, while listening, to think of either the gramophone or the horn, as the sounds come from the reflector, and the effect is much more real and natural.

I believe the application of this method of "acoustical filtration" may be applied by ingenious mechanics in such a way as to do away with the necessity of building up such an array of tubes as is seen in the figure. The method enables one, in a room of moderate size, to listen to pure music. One cannot help observing how it mellows a voice that, heard in the ordinary way, sounds harsh

(from the production of overtones of high pitch), and how it brings out the pure tones of the string instruments. The various instruments in an orchestra sound better. Everything is reduced in proportion, and, to use an illustration from art, it is like passing from one of Etty's huge pictures to a delicate and beautiful Messonier, in which one sees and appreciates every detail in an area of small dimensions. JOHN G. MCKENDRICK.

A New Variety of Zebra.

WILL you kindly allow me a little space to direct attention to a new and very interesting variety of Grant's zebra, shown in the accompanying photograph sent me by my friend Mr. C. W. Hobley, C.M.G., commissioner at Nairobi, East Africa? The specimen, writes Mr. Hobley, "was obtained by Mr. G. H. Goldfinch, assistant game ranger of the East African Protectorate, a few months ago in the neighbourhood of the Rift Valley. The

animal has a "big whitey patch in the middle of the back, and it came out of a herd which were all the same. I suppose it is a Mendelian 'sport,' which has become dominant in that particular herd, like the white waterbuck on the Euaso Nyiro, north of Kenia."

I propose to call this variety in Mr. Pocock's terminology, *E. quagga*, var. Goldfinchi, or in the old terminology, *E. Burchelli*, var. Goldfinchi. Mr. Hobley adds that the print is a little dark, as "the stripeless saddle on the body is very markedly white in the skin itself."

April 11. WILLIAM RIDGEWAY.

Implements of Moustierian Type from the Rock of Gibraltar.

IN a paper read before the Royal Anthropological Institute on March 7 (NATURE, March 16, pp. 100–101) I gave an account of recent cave-exploration at Gibraltar. In one of the caves thus described, the discovery of various mammalian remains was recorded, together with that of human bones, pottery, and stone implements.

In regard to the latter, a close comparison was made with cave implements, and the similarity of certain examples to implements of the Moustierian type was remarked. But a guarded opinion was given, and this caution, I am now glad to state, seems to have been excessive.

On March 31 Dr. Allen Sturge very kindly examined the specimens with me, and he allows me to record his opinion on four implements submitted to him. The conclusions were fully borne out by comparisons with specimens in Dr. Sturge's magnificent collection. Of the four implements, three (Nos. 2, 7, 13) are judged to be definitely of Moustierian type; the remaining one (No. 15) is either "Moustierian" or "early Aurignacian" (the next and following stage).

Thus out of eleven stone objects (from the cave in question), that are undoubtedly implements and not mere splinters, four are distinctly Palæolithic, and of an early period. So far as I know, Palæolithic implements have not been previously recognised or recorded in connection with the caves of Gibraltar. Moreover, those now mentioned were not accompanied by any polished implements or by any metal objects.

The recognition of Palæoliths of the Moustierian type gives some ground for hope that eventually the whole series of cultural epochs may be established for the caves at Gibraltar, as has been done elsewhere. Further, the discovery of a human skeleton of that period might throw a flood of light on the significance of the Forbes Quarry skull. In any case, exploration will be resumed with increased zest in view of these possibilities.

In conclusion, I would point out that Obermaier seems to hold the opinion that the associations of culture with fauna will be found to differ in the Mediterranean area and in western or central Europe (*L'Anthropologie*, 1909, Tome xx., p. 520). My investigations have already suggested a marked similarity between the Gibraltar caves and some of those at Mentone. Probably the northern limit will be found to include Les Eyzies. Lastly, the preceding remarks are written with full appreciation of the weight of Commont's remarks (1910) as to the significance of isolated examples of implements referable to a particular age. W. L. H. DUCKWORTH.

Anthropological Laboratory, New Museums,
Cambridge, April 5.

Damage done to Skulls and Bones by Termites.

THE extensive damage done to skulls and bones generally in many of the graves of Egypt and Nubia has been attributed to beetles, the bodies of these animals having been found in the earth which is invariably associated with the damaged area, the latter being, in fact, always covered with earth unless it has been knocked off during removal of the skull from the grave.

There is good reason, however, for believing that the damage is the work, not of bettles, but of termites, which still exist in these countries.

These animals, as is well known, never work without covering all their operations with a tunnel or ramification of tunnels composed of earth or grains of sand firmly stuck together by some secretion from the ants themselves. Under cover of these earthworks, they devour whatever substance they have built over, and the destruction is sometimes so complete that nothing but a shell of earth remains, the substructure having been entirely eaten away. In such cases the original form of the destroyed article may be distinctly seen, as the mud covers it in a fairly thin uniform layer, following all its lines and contours. A good example of this was seen at Koshtamna in Nubia, about seventy miles south of Aswan. Here a small wooden statue of a king was still standing in its original position in a tomb chamber, but the crown and more prominent features of the face, completely covered though they were with mud, still preserved the outlines of the form beneath. When, however, the mud was removed, it was found that the statue upon which it had been built was almost completely destroyed, only fragments of the wood being left here and there.

In the case of skulls and bones precisely the same thing happens. A skull is found covered with mud firmly stuck on, and with the traces of the white ants' tunnels running through. If the mud is removed, large areas of the cranial walls may be found to have disappeared altogether. In less exaggerated cases, holes will be seen with white, gnawed edges, or perhaps only the surface of the bone has been attacked. The cranial sutures are a favourite site for the commencement of the termites' operations.

The presence in some cases of the dead bodies of small reddish beetles embedded in the mud on such skulls led to the not unnatural conclusion that they were the authors of

the mischief. The following facts, however, show this to be incorrect.

In the first place, the tunnels, which run in all directions beneath the cake of mud, are too small to contain the beetles found embedded in it.

Secondly, the beetles are found in many other parts where there is no sign of damage to the bone, and quite commonly, in the case of mummies, beneath the linen wrappings where these are in contact with the skin, in which situation they are frequently embedded in the resin or bitumen which has been used in the mummifying process. In these situations there is, of course, no mud whatever, while the damage to the bones is *always* associated with earthworks and tunnels.

Thirdly, though the same earthworks appear in every direction in the grave containing affected bones, on the roof, walls, coffin, &c., no beetles are ever found anywhere in association with such workings except on the body.

Fourthly, in mummified bodies, where the wrappings, soaked in bitumen, are so hard as effectually to have excluded even the ravages of white ants, the works of which may, nevertheless, cover the *outer* surface of such wrappings, beetles are still found in and about the mouth and nose of the mummy, some stuck to the teeth, others to the linen with which the mouth is filled, but *not* in this case on the outer surface of the wrappings, where they ought to be if they were the authors of the earthworks which cover the mummy cloths.

From these facts it seems clear that the beetles were present before the process of mummification was complete, that they became covered over when the body was wrapped, or possibly were not hatched until this was complete, and so are found stuck to the resinous wrappings. In cases where less bitumen or other substance was employed, and the body was merely wound in cloths, the white ants were able to make their way through these with the greatest ease. While doing so they would come in contact with the beetles which had been included in the wrappings, and these would then perforce become embedded in the mass of earth brought up by the termites. It is noteworthy that *complete* bodies of beetles are seldom or never found in the mud. If carefully examined, their heads, legs, and under parts are usually gone, only the tough wing cases remaining, and these are so strong that to a certain point they will resist crushing with the fingers. On the other hand, beetles complete, so far as the naked eye can detect, in every part, even to the delicate antennæ, have been found under the wrappings, and particularly in the neighbourhood of the mouth and nose. The inference from this is, of course, that the white ants devoured the softer parts of the beetles when they found the bodies of these animals in their path, leaving the hard portions stuck in the mud of their buildings.

What is the genotype of X . . us Jones, 1900, based upon a species erroneously determined as *albus* Smith, 1890?

Statement of Case.—Jones proposes a new genus *X . . us*, 1900, type species *albus* Smith, 1890.

It later develops that *albus* Smith, 1890, as determined by Jones, 1900, is an erroneous determination.

What is the genotype of *X . . us*, 1900; *albus* Smith, 1890, or the form erroneously identified by Jones as *albus* in 1900?

Discussion.—The nomenclatorial problem expressed in the caption of this note is solved in two diametrically opposite ways by different authors.

Some writers maintain that the original *albus* Smith, 1890, is the genotype, while others maintain that the genotype is represented by the species actually studied by Jones and misdetermined as *albus* Smith.

Cases of this general nature have given rise to considerable confusion in nomenclature, and several such cases have been referred to the International Commission on Nomenclature for opinion.

At the last meeting of the Commission, the principles involved came up for discussion, but it was impossible to reach a unanimous agreement. On account of the differences of opinion, the secretary was instructed to make a careful study of a number of cases, and to report upon the same to the Commission.

It is not difficult to foresee that, no matter how the cases are finally decided, great dissatisfaction will arise among zoologists, because the opinion rendered is not the direct opposite of what it eventually will be.

Recognising that this is one of the most difficult cases that has ever been submitted to the Commission, and recognising the fact that, regardless of our action, we shall probably be criticised more on the basis of our decision on this case than because of any other opinion that we have rendered, I am desirous of studying at least 100 cases, if possible, that would come under such a ruling, before my report is formulated.

In view of the foregoing premises, I respectfully request zoologists in different groups to direct my attention to as many instances of this kind as possible with which they are acquainted in their different specialities. Further, since the arguments on both sides of the problem appear to be almost equally valid, it does not seem impossible that the final decision will have to be based upon the arbitrary choice between the two possible rulings, and on this account I am desirous of obtaining all possible arguments on both sides as they occur to different zoologists, and also any personal views based upon convenience or inconvenience, or other grounds, which may be held by different colleagues.

I will hold the case open at least until September 1, for the presentation of arguments by any persons who may desire to submit their views.

C. W. STILES,
Secretary of the Commission.
April 4.

A Kinetic Theory of Gravitation.

As one who for many years has been attracted by the problem of gravitation, I was greatly interested in Mr. C. F. Brush's "Kinetic Theory of Gravitation" (NATURE, March 23), and in Sir Oliver Lodge's letter relating thereto (NATURE, March 30).

About three years ago I made an attempt to examine how far gravitation might be accounted for by waves of compressional type propagated through the æther (cf. *Phil. Mag.*, January, 1909). Before any such theory can be admitted, even as a working hypothesis, it must be shown by rigorous dynamical methods to be capable of accounting for gravitational attraction. This in itself involves no elaborate analysis, though questions arise as to the fundamental nature of matter and of its motion with respect to the æther.

It appears, in opposition to what might readily be supposed, that Mr. Brush's assumption of a directionally indifferent (isotropic) distribution of waves is not needed; a single progressive train of plane-waves would answer equally well. The real difficulties of the theory are encountered when we consider the several effects, other than gravitational attraction, which might arise from the impact of compressional æthereal waves upon atomic matter. It has to be shown that, under admissible assumptions, the *direct* action of the waves would not give rise to any observable phenomena of motion, and that the heating effect might be *nil*, or small enough to escape observation. Other points no less important have also to be considered: they are dealt with at length in my paper.

I fully concur in Sir O. Lodge's objection to regarding the atom "as a foreign substance—a sort of 'grit' in the æther," and, in the paper referred to, matter was treated as of purely æthereal constitution, the motion of a material body through the æther being regarded as unaccompanied by any bodily transference of *ultimate* matter through finite distances. As to whether the gravitative property of matter is essentially bound up with its constitution, or is due to something external, I think Sir O. Lodge will agree that, notwithstanding metaphysical prepossessions (in which I largely share), we should yet keep an open mind. The real solution of the question is perhaps very different from what we are reasonably entitled to expect!

It may be mentioned, however, that some experiments now in progress seem likely to add very considerably to the difficulty of accepting a compressional-wave theory of gravitation.

C. V. BURTON.
Boar's Hill, Oxford, April 2.

DEVELOPMENT OF BRITISH FORESTRY.[1]

THE work on the development of British forestry by Mr. A. C. Forbes, Chief Forestry Inspector to the department of Agriculture for Ireland, will be welcomed by all interested in the question of afforestation. The author deals with his subject in a lucid and convincing manner. To add to the interest of the book, a large number of excellent photographs illustrating the various types of tree-growth in different soils and localities has been included. These alone form a remarkable and instructive photographic survey of the forest conditions not only within the British Empire, but also to some extent on the Continent.

FIG. 1.—Two-storied Beech Wood, Chiltern Hills. From "The Development of British Forestry."

The opening chapter deals with the national aspects of forestry, and here Mr. Forbes has gone to the very foundation of the subject from historical and geographical points of view. The following chapter deals with the forest requirements of the United Kingdom. It is pointed out that, in comparison with other countries, we have the lowest percentage of total land-surface under woodland, with the highest consumption of imported wood per head of population. The writer calculates that, in addition to the three million acres already under trees, we should require to bring another four million acres or so under forests, giving a total of at least seven million acres, equal to about 10 per cent. of the land-surface. The timber production, forest laws, and forest area of other countries are carefully considered in forming an estimate of the requirements of the United Kingdom. Chapter iii. is on the relation of agriculture to forestry development, and here the author shows himself to be equally at home in agriculture and forestry. This is a most valuable chapter, and shows how the area under trees may be extended without unduly disturbing the agricultural value and produce of the country. Chapters iv. and v. deal respectively with climate and tree-growth, and soil and surface conditions in the British Isles; while chapter vi., on the need for improved methods and practice in British forestry shows how vast improvement could be made in our existing woodlands by the adoption of more scientific and up-to-date methods. Chapter vii., on the economic value of the British forest flora, gives a very valuable and interesting account of the sylvicultural characteristic of the trees generally cultivated in Britain. No one is better able to deal with the financial aspects of British forestry than Mr. Forbes, and chapter viii., which treats of this subject, should prove of the greatest interest to all planters.

The final chapter entitled "The State and Private Ownership of Woods" comes as a fitting termination to a work on the development of British forestry. It is here pointed out how the State, and the State alone, can bring about the much-needed improvement in afforestation of the country. The author, however, clearly points out that the cooperation of the individual is necessary if we are to achieve permanent and all-round improvements. In his own words:—"The co-operation of the individual is as necessary in national forestry as in the creation and development of industries, and the idea that the State can entirely take the place of the individual wood-owner is equally absurd as the idea that the latter can succeed without the assistance of the State."

FIG. 2.—Selection Felling in Chiltern Hills Beech Wood. From "The Development of British Forestry."

All through this excellent book the author is moderate in his views and logical in his reasoning. Conclusions are arrived at only after very careful

[1] "The Development of British Forestry." By A. C. Forbes. Pp. xi+274. (London: E. Arnold, 1910.) Price 10s. 6d. net.
"English Woodlands and their Story." By H. Townley. Pp xiii+309. (London: Methuen and Co., Ltd., n.d.) Price 15s. net.

consideration based on personal study and experience. The volume contains many tables of statistics, and is also provided with an excellent index.

"English Woodlands and their Story," by Mr. Houghton Townley, is an interestingly written and well-illustrated work. The book is written more for the forest-lover and student of nature than for the technical forester, but it may be warmly recommended to all interested in any way with trees and forests. The history, traditions, and associations of the old English woodlands and forests are set forth in a most fascinating manner. The laws of olden times, when forests were principally used for the chase, are interestingly described, as well as all matters of historical interest connected with the various forests of England. Nothing could be more interesting than the perusal of this work, which is written in a most readable fashion, and, though not intended as a textbook on forestry, its perusal cannot fail to be of the greatest interest to all foresters and those connected with the management of woodlands, as well as all forest-lovers and students of nature.

THE TROGLODYTES OF EUROPE.[1]

In his excursions into the byways of archæology and primitive culture Mr. Baring-Gould is always interesting and instructive, and in his present book, dealing with the cave-dwelling troglodytes and the cliff castles of Europe, he has found a subject hitherto little explored and well suited to his powers. The moral of the book, though it is nowhere clearly defined, is the essential unity of human culture, man always adapting to his use the material which his environment supplies.

The chalk formation, traceable from the north of Ireland to the Crimea, and from the south of Sweden to Bordeaux, a distance of about 11,140 geographical miles in one direction, and 840 in the other, with its characteristic cavities and the facility of supplementing them by artificial means, naturally provided habitations for prehistoric man; while in other places tufa, volcanic breccia, and sandstone took its place. Palæolithic man shows his artistic powers not only by graving representations of the men and fauna of the period on ivory and bone, but in the wall-paintings of shelters like those at Les Combarelles and Font-de-Gaume he provides a veritable picture gallery. In a cave recently explored have been discovered actual pieces of sculpture of extinct beasts in the round. The preservation of these frescoes and sculptures is due to the fact that the caves have been sealed up from time immemorial, and subjected to no invasion by man or beast or to any change of air or temperature; further, the primitive lamps fed with melted fat could not produce smoke sufficient to discolour ceiling or wall. The genuineness of these paintings is assured by the circumstance that some are partially glazed over and some half obliterated by stalagmitic deposits. This prehistoric savage type of life survives among modern cave-dwellers in Cornwall and in the strange family of troglodytes described by Sir A. Mitchell, who discovered them dwelling in a state of wretched squalor on the shore of Wick Bay. Among subterranean dwellings the wonderful labyrinthine town ascribed to Og, king of Bashan, at Edrei, in the Hauran, is perhaps the most remarkable example. The best parallel to it in Europe is that strange French town, Trôo, on the river Le Loir, which traverses the fertile upland plain of Beauce, and falls into La Loire at Angers. Here the whole height is like a sponge, perforated

The Ruined Monastery in the Rocks, Nottingham Park. From "Cliff Castles and Cave Dwellings of Europe."

[1] "Cliff Castles and Cave Dwellings of Europe." By S. Baring-Gould. Pp. 324. (London: Seeley and Co., Ltd., 1911). Price 12s. 6d. net.

with passages giving access to cells, and store-chambers, most of the houses being wholly or partly underground. In this country we have examples of similar constructions in the Dene-hole chalk quarries of Darenth Wood and those near Chislehurst, the Cornish excavations known as Fogous, the cave in the Isle of Egg, one of the Hebrides, the scene of the terrible massacre of the Macdonalds by the Macleods, and that on Rathlin Island, where a similar tragedy occurred during the campaign of Essex in 1575, of which Froude supplies a graphic narrative.

From structures such as these Mr. Baring-Gould passes on to the cliff castles occupied by the ruffianly Routiers and Free-Companions in France, and the many caves and similar shelters tenanted by hermits and ascetics, robbers, and outlaws in other parts of Europe. The church has also utilised many subterranean excavations of the same kind, such as the monolithic chapel of St. Emilion in Dordogne, and the still more remarkable underground churches at Plouaret in Côtes-du-Nord, and the Spanish example at Cangas-de-Ones, near Oviedo, where a prehistoric dolmen is used as a crypt.

The value of this interesting, if rather discursive, book is much increased by the series of excellent sketches, most of which were drawn by the author on the spot in his exploration of this remarkable series of monuments.

MAJOR GEORGE LAMB, I.M.S.

We regret to record the death, which took place at Edinburgh on April 11, of Major George Lamb, director of the Pasteur Institute of India, Karauli (Punjab), in his forty-second year. He was a distinguished graduate of the University of Glasgow, and for some time demonstrator of anatomy in that university, but resigned this post in order to enter the Indian Medical Service. From the first he strenuously applied himself to research, and the extent and nature of his published work strikingly attest his great ability and originality, and his indefatigable industry. Within a few years after joining the service, he had made his mark by researches on Mediterranean fever in India, typhoid fever, and anti-typhoid vaccine, and other subjects connected with the scientific treatment of disease. He was subsequently continuously employed in important scientific inquiries initiated by the Government of India.

Nearly ten years ago Major Lamb was appointed head of the laboratory for the investigation of snake poisons, and became one of the chief authorities on this subject. The results of his observations appeared in about a dozen papers, which deal with the venoms of Russell's viper, the cobra, and the banded krait, their action on the blood plasma and corpuscles and on the nervous system, and with the specificity of their antisera. He was joint author (with Dr. C. J. Martin, F.R.S.), of the section on "Snake Poison and Snake Bite" in the "System of Medicine," edited by Sir Clifford Allbutt and Dr. Rolleston.

Major Lamb's greatest work was done in connection with the Plague Commission to which he was appointed, as senior member, in 1905. He was responsible for the carrying out of that detailed and widespread inquiry into the mechanism of the epidemic spread of plague in India, the results of which have been published in five reports, the last only recently issued. He initiated and throughout bore a prominent part in the long series of experiments and observations which resulted in the conclusive proof of the transference of plague from rat to rat, and from rats to man by the agency of fleas.

Since his appointment as director of the Pasteur Institute of India, which took place when the plague inquiry was nearing its close, Major Lamb devoted himself largely to the subject of hydrophobia, and introduced important modifications in the treatment of the numerous cases annually dealt with at that institute.

Major Lamb has left an enduring mark upon three main lines of research—snake venoms, plague, and hydrophobia—each of outstanding importance in Indian medical work, to which he devoted himself successively with characteristic zeal, patience, and skill. His frank and genial manner, his clear grasp of, and self-sacrificing devotion to, the work he had in hand called forth, in those privileged to work with or under him, loyal and enthusiastic cooperation. His wide knowledge of medical science in its application to Indian problems will be much missed in medical and scientific circles both at home and in India, and his friends will deplore the loss of one who had a most genial and captivating personality.

J. H. A.

NOTES.

A preliminary programme has been issued for this year's meeting of the British Association, which, as already announced, is to be held at Portsmouth on August 30 and following days. The opening meeting will be held in the Town Hall on Wednesday evening, August 30, when Sir William Ramsay, K.C.B., will assume the presidency and deliver his inaugural address. In the same hall the first evening discourse will be delivered on Friday evening, September 1, by Mr. Leonard Hill, F.R.S., on "The Physiology of Submarine Work," and the second on Monday evening, September 4, by Prof. A. C. Seward, F.R.S., on "Links with the Past in the Plant World." The reception room and administrative offices during the meeting will be established in the Connaught Drill Hall, which is centrally situated close to the Town Hall, and within easy access of all the meeting rooms which will be occupied by the sections. The president will have the assistance of a strong body of representatives of the administrative, ecclesiastical, naval and military interests of the town and neighbourhood, headed by H.R.H. Princess Henry of Battenberg and the Mayor, Alderman T. Scott Foster. An afternoon reception and an evening *fête* are announced to be given by the Mayor, and facilities will be arranged for members to visit sites and objects of scientific, historical, and national interest in Portsmouth and the neighbourhood.

A committee for the study of the sea was appointed in 1909 by the Italian Society for advancement of science. Its work was so active and promising that a few months later the committee was converted by an Act of Parliament into an institution of the Italian kingdom. The Regio Comitato Talassografico Italiano is to be concerned with investigations of the Italian seas from the physical and chemical points of view as well as from the biological. Great importance will be attached to practical questions concerning the navigation and the fisheries. Investigations of the high atmosphere will also be made in connection with aviation. The president of the committee is the Marine Minister, and representatives of the chief institutes, academies, and societies which take interest in sea investigations have been appointed as members. In addition the committee has a scientific staff of its own; it receives a yearly grant from the Italian Government of 60,000 lira (2400*l.*); and the ships for the cruises are supplied by the Italian Royal Navy. Four cruises in the Adriatic sea have

taken place already, the programme of which was agreed upon with the delegates of the Austrian Government. We understand that a fifth cruise will soon start.

It is announced that Mr. J. H. Grisdale has been appointed director of the Dominion Government's Experimental Farm System, in succession to Dr. William Saunders, C.M.G., who has retired.

The death is announced of Colonel I. C. Walker, who from 1881 to 1890 was Chief Conservator of Forests in Madras, and from 1895 to 1898 Inspector-General of Forests in Mysore.

We regret to see the announcement of the death, at ninety-one years of age, of Mr. T. Rupert Jones, F.R.S., formerly professor of geology at the Staff College, Sandhurst, and the author of many papers and essays on geological subjects.

At the meeting of the Faraday Society to be held on Tuesday, May 2, Mr. A. Scott-Hansen, the well-known Norwegian engineer, will deliver a lantern lecture on "Hydro-electric Plants in Norway, and their Application to Electrochemical Industries." On the same evening a paper is down for reading by Mr. Verdon Cutts, of Sheffield, entitled "Electrometallurgy in the Steel Foundry."

On Thursday next, April 27, Prof. R. W. Wood, of the Johns Hopkins University, will begin a course of three lectures at the Royal Institution on "The Optical Properties of Metallic Vapours," these being the Tyndall lectures. The Friday evening discourse on April 28 will be delivered by Prof. W. M. Flinders Petrie on "The Revolutions of Civilisation," on May 5 by Prof. M. O. Forster on "New Organic Compounds of Nitrogen," and on May 12 by Prof. William Stirling on "Biology and the Kinematograph."

The annual conversazione of the Selborne Society will be held on May 5, in the theatre and halls of the Civil Service Commission, Burlington Gardens, W. This year there will be very interesting exhibits of rural industries, including the prehistoric occupation of Flint Knapping, whch still survives in Suffolk, where gun flints and strike-a-lights for tinder boxes to export to tropical countries is still carried on. The president, Lord Avebury, will take the chair in the theatre, and a lecturette will be given on "The Eggs of Butterflies and Moths," illustrated by photographs by Mr. F. Noad Clark.

The 1912 Boston Electric Show will be held in Boston, Massachusetts, U.S.A., from September 28 to October 26, 1912. It will occupy the whole of the great Mechanics' Building, with more than 105,000 square feet of exhibit floor space and accommodations for more than 100,000 visitors at one time. This building is the largest exhibition structure of the kind in the world. The organisation of this electric show, the financial responsibility of its management, and the scope and policies of the great undertaking, are under the auspices and supervision of the Edison Electric Illuminating Company of Boston.

At the Plymouth Laboratory of the Marine Biological Association, the usual Easter vacation course in marine biology was conducted by Prof. W. Garstang, and was attended by seventeen students from Oxford, Cambridge, the Imperial College of Science, Leeds University, and Bedford College. Dr. C. Shearer, of Trinity College, took a class of six Cambridge students to Plymouth for a course of work on experimental embryology. Artificial parthenogenesis of the eggs of *Echinus esculentus* was successfully carried out by the students, and a number of experiments on the lines of work of Loeb and Driesch were repeated. As is usual at this time of the year, the research tables have been well occupied, eleven visiting naturalists, in addition to three on the permanent staff, having been engaged in zoological investigations.

The first non-stop flight from London to Paris was made, on April 12, on a Blériot monoplane by M. Pierre Prier in 3h. 56m. M. Prier, who is the chief instructor of the Blériot School at Hendon, left that ground at 1.37 p.m., taking a course for Dover *via* Hampstead, Highgate, Greenwich, Chatham, and Canterbury. There was a slight north-east wind as he started, which changed to a north-west by the time he reached Dover, at 2.50 p.m. Thirty minutes later he was over Boulogne, and steering a straight course over Abbeville and Beauvais for Paris, where he arrived at 5.33 p.m., making a perfect landing in front of the Blériot sheds at the Issy-les-Moulineaux aviation ground. The height maintained throughout was between 1500 and 2000 feet, except at the Channel crossing, when he rose to more than 3000 feet. The machine was fitted with a 50 horse-power Gnome motor and three special tanks for an extra supply of petrol, of which, however, barely half was used. M. Prier, who found his way by means of a compass designed by M. Blériot and a map, suffered no inconvenience throughout the journey except slight inflammation of the eyes, due to his neglecting to equip himself with goggles.

The council of the Central and Associated Chambers of Agriculture has appointed a committee to report upon the desirability of the adoption of uniform weights and measures. It is not yet clear how this inquiry will be conducted. On previous occasions when local bodies have been consulted, the reports received from them have been of a contradictory character, so that it has appeared hopeless to propose a system likely to meet with general satisfaction among agriculturists. It is improbable that the metric system would meet with much support. An opinion appears to prevail in some quarters that the weights specified in the Corn Returns Act of 1882 for a bushel of wheat, barley, and oats, respectively, are in some way prejudicial to the cereals market in this country. There is also a proposal to apply the term "hundredweight" to the cental of 100 lb., and to fix the stone at 10 lb. instead of 14 lb., as a preliminary to decimalising our present system of weights. A Select Committee of the House of Commons appointed to inquire into the various weights and measures used in the sale of grain reported in 1893, after a lengthy investigation, in favour of the retention of the weights specified in the Corn Returns Act, and also recommended that the sale of all cereals should be in terms of the hundredweight of 112 lb., and that no other weight or measure of capacity should be referred to in any sale.

Dr. John Duncan Gregorson, whose death is reported to have taken place in the recent massacre of the British mission on the Assam frontier, was born in Lochgilphead, Argyllshire, in 1871. He entered the University of Edinburgh in 1889, and graduated M.B., C.M., in 1894. After a course of post-graduate study, he was for several years in practice in Leytonstone, but formed a desire for work in the domain of tropical diseases, which an offer made to him about eight years ago enabled him to fulfil. During this period he was medical officer to a group of tea estates located around Tinsukia, in Upper Assam, and two years ago published, in the Journal of Tropical Medicine, a paper giving some interesting notes on the methods used in combating disease among the coolies imported from

India to work on the tea gardens. The population under his care amounted to about 25,000, consisting of many races from widely different parts and climates of India, scattered over a large extent of country in settlements, each containing about 2000 inhabitants. The part of Assam in which Dr. Gregorson laboured has a climate admirably suited for the spread of malaria and ankylostomiasis, which, along with cholera and dysentery, were the chief diseases he had to combat. His work was carried on under very considerable difficulties in regard to the extent of country to be traversed and number of cases to be seen and treated, but he dealt with the various problems presented in a vigorous and effective manner. His success was evidenced by the respect in which he was held throughout the district, and by his having been invited to sit on a Government commission to inquire into the conditions at a garden where the death-rate had been exceptionally high.

The Secretary for Scotland has appointed the following to be a committee to consider and report on certain questions relating to forestry in Scotland, viz.:—Sir John Stirling-Maxwell, Bart. (chairman), the Right Hon. Lord Lovat, C.B., K.C.V.O., the Right Hon. R. C. Munro-Ferguson, M.P., Mr. John D. Sutherland, Sir John Fleming, Sir Matthew Wallace, and Mr. R. H. N. Sellar. Mr. H. Warre Cornish, Dover House, Whitehall, S.W., will act as secretary to the committee. The terms of the reference to the committee are as follows:—"To report as to the selection of a suitable location for a demonstration forest area in Scotland; the uses, present and prospective, to which such area may be put (including the use that may be made of it by the various forestry teaching centres in Scotland); the staff and equipment required for successful working; the probable cost; and the most suitable form of management. To report as to any further steps following upon the acquisition of the said area which, in the opinion of the committee, it is desirable should be taken with the view of promoting sylviculture in Scotland, due regard being had to the interests of other rural industries."

In *The National Geographic Magazine* for February Mrs. M. L. Oliver gives an interesting account of the remarkable Snake Dance performed by the Hopi Indians at the pueblo town of Oraibi, illustrated by a valuable collection of photographs. This is one of the fertility rites fully described by Prof. J. G. Frazer in the last edition of his "Golden Bough," the legends indicating that the snakes, the progenitors of the tribe, are conciliated as representing the earth spirits. The dance is performed by members of the Antelope clan and by the Snake priests. The latter dance with live rattlesnakes in their mouths, and these at the close of the rite are released at the four points of the compass to wander where they please in the desert. The dance is followed by ceremonial ablution and the liberal use of a powerful emetic to remove the taboo from the officiants.

The Sarawak Museum Journal, of which the first number was issued in February last, makes a good start with a collection of interesting papers describing the resources and people of the State. In the ethnological notes we find a full account of the remarkable Tau Tepang superstition which is current among the sea Dyaks, and particularly among those tribes which are furthest removed from civilisation. The legends of its origin are not uniform. One story tells that a great snake once devastated the land, and that its spirit announced that anyone who succeeded in eating its tongue would gain the hereditary faculty of becoming a Tau Tepang, that is to say, a person whose head possessed the power of leaving its body, and after working mischief during the night, could return to its owner in the morning. Hence all kinds of evil are attributed to such people, who are rigorously excluded from intercourse with their neighbours; and every paddy farm must be carefully guarded with charms, which contain sharp bamboo spikes intended to pierce the face and eyes of any of the Tau Tepang community who may attempt to injure the crops.

Franz de Zeltner gives in *L'Anthropologie* (tome xxii., p. 1) an illustrated account of some caves containing mural paintings which he has discovered in the French Sudan, near Bamako, Boko, Boudoufo, and Kita. They occur near the entrance of rock shelters, so that no artificial light was needed to make them; the colours employed are yellow ochre, red, indigo blue, black, white, and rarely pink; they were laid on with the fingers, as there are no brush marks, and there is no evidence that grease was used in mixing the colours. He found only eight realistic figures, and these occur in only one shelter; everywhere geometric designs predominate. The conventional representations of man and animals recall the rock engravings of Sahara and Egypt. There is no correlation between the different signs, and their grouping appears to be quite haphazard. The author does not believe that the caves ever were dwelling-places, and he definitely rejects the hypothesis of a magical and totemic origin of the painting; indeed, he states that "nothing in the traditions or actual life of the blacks confirms it, quite the contrary, since the representation of their protecting animal is forbidden to them as well as contact with it." New discoveries are recorded of rock pictographs in Aragon and Estremadura (*L'Anthropologie*, *loc. cit.*, p. 119). At present only a preliminary survey has been made; the paintings appear to correspond with the later phases of palæolithic decorative art, indeed, many of them recall the conventional designs of Mas d'Azil, which mark the decadence of the great art of palæolithic times. No traces were found of a neolithic or any subsequent period.

Prof. Pillsbury contributes an interesting paper to the current number of *The Psychological Review* on the place of movement in consciousness. In America, the modern tendency to explain mental processes in terms of movement may be said to have begun with James's well-known theory of the emotions. It has since been extended by Dewey and his school, and has been lately utilised to give impetus to pragmatism in philosophy. Space, even from the time of Berkeley, has received a motor interpretation. Time and rhythm have also been referred to movement. Even memories have been explained as a reinstatement of past movements, and the next logical step would be, as Prof. Pillsbury points out, to suggest that the true quality of sensation is motor. "All that is necessary is to assume that each sense organ is connected with definite muscles, that these muscles are excited whenever the sense organ is stimulated, and that the colour or tones that we see or hear have their origin in some group of muscles rather than in a sense organ or in the cortex." The author points out that nothing is gained by such conceptions if we hold the current view that movements themselves are only known through sensations. He cites the results of recent experiments on the motor cortex of living man, which show that the motor impulses originating from the motor cortex contribute nothing directly to consciousness. "Granted that movements are only known by the kinæsthetic sensations, to translate all conscious qualities into motor terms merely transforms all other sorts of sensation into the one sense, and that a sense

relatively poor in qualities." But where the motor theory most completely breaks down is when it attempts to explain functional problems. Meaning, thinking, recognising, have all been tentatively explained in terms of motor theory. Now "movements in and of themselves have no meaning, are not immediately recognised nor understood. These functions require just as much explanation when they attach to movements as to any mental process." Function is evidently something more than movement; use is something more than structure. As the author points out, "more important than either sensation by itself or movement by itself is the fact that consciousness is always an organised system."

In *The Entomologist's Monthly Magazine* for April Mr. G. H. Verrall adds one hundred species of Diptera to the British list. Of these, seven are entered as new species, but since there is no diagnosis, these would appear to be *nomina nuda*, which may be appropriated by anyone else.

The Bergens Museum *Aarsberetning* for 1910 contains a brief account of the recent Atlantic cruise of the *Michael Sars*, financed and directed by Sir John Murray. The collections, it appears, are to be worked out at the Bergen Museum, where the types of new forms will be preserved.

According to an article by Dr. Bather in the March number of *The Museums Journal*, the Muses are to have no roof over their heads in some of their habitations, for the movement in favour of open-air museums is stated to be making distinct progress. Such establishments will be, of course, for the display of antiquities not liable to deterioration by exposure to the weather, and they will certainly have the advantage of cheapness. It is satisfactory to note that Dr. Bather considers the exhibition of local objects should be the main function of local museums, their first duty being "to interest the people of their city or county in their own history."

The *Bulletin Scientifique de la France et de la Belgique* is making a praiseworthy effort to advance the assimilation of current scientific literature by publishing an annual "Bibliographia Evolutionis," which is to record not only the titles of books and papers, but likewise to give a *précis* of their contents. The present issue, of which we have been favoured with a copy, deals with the year 1910, and contains 345 items. The compilers are to be congratulated on the celerity with which they have accomplished this work, and are entitled to the gratitude of all students of subjects connected with evolution, both as regards zoology and botany.

In connection with the arrival of the first living elephant-seal at our own Zoological Gardens, to which reference has been made in Nature already, it is interesting to note that, according to *Science*, half-a-dozen young elephant-seals from Guadalupe Island, on the Californian coast, have been received at the New York Aquarium in excellent condition. Although not more than nine months old, these young monsters average about 250 lb. in weight, and measure from 4½ to 5 feet in length. Although described as a distinct species (*Macrorhinus angustirostris*), the Guadalupe sea-elephant is identified by Mr. Rothschild with the typical *M. leoninus* of Juan Fernandez, the Crozet form, to which the London specimen belongs, being regarded by him as a race of the same species.

The habits and life-history of pycnogonids (Pantopoda) form the subject of an illustrated article by Mr. H. Prell in the third part of the Bergens Museum *Aarbog* for 1910. If kept in cold water, the members of the genus Nymphon flourish in aquariums. All of them crawl, but a few are also able to swim by the aid of swimming-hairs, which are more strongly developed in males than in females. They feed entirely on Hydrozoa, more especially Campanulariidæ, and the curious mode in which these organisms are seized and devoured is well shown in the illustrations. The species of Pycnogonum which are parasitic on sea-anemones, the juices of which they suck, are, on the other hand, much more difficult to keep in confinement.

The accepted classification of the brittle-stars (Ophiuroidea), according to Mr. H. L. Clark in a paper, of 302 pages, published as Bulletin No. 75 of the U.S. National Museum, is little short of an absurdity, nor has any attempt been made for the last thirty years to put it on a rational basis. Unfortunately, the author has not found himself in a position to remedy this unsatisfactory state of affairs, and he has therefore followed a classification based on a compilation of the work of Lyman and some of his successors. Mr. Clark's paper relates to the North Pacific representatives of the group, of which an enormous collection, comprising more than 40,000 specimens, referable to about 190 species, were at his disposal, the bulk of these having been collected by the *Albatross* during various cruises to and from Alaska, Bering Sea, and Japan. Out of 189 species, no fewer than 112 are from south Japanese waters, to which most of them are restricted. This Honshu fauna, as it is called by the author, is evidently related to the still richer Oriental ophiurid fauna, although only about a dozen species are at present common to the two. The Bering Sea fauna is very distinct from that of Honshu, although the two are connected by a group of sixteen common species. Other points brought out in the monograph are the occurrence of West Indian species in the North Pacific, and evidence in favour of the existence of a distinct circumpolar fauna.

A valuable paper on the post-larval development and minute anatomy in the genera Scalpellum and Ibla has been lately published by Dr. F. H. Stewart in the Memoirs of the Indian Museum (vol. iii., No. 2, 1911). The author has been able to supplement, in some important particulars, the accounts of cirripede development as given in Darwin's classical Ray Society Monograph and in Hoek's well-known contribution to the *Challenger* Reports. There are four plates of excellent drawings representing stages between the cyprid-larva and the adult, mostly taken from species of Scalpellum. It will be remembered by students of the barnacles that while Darwin and Hoek had stated the dwarf male forms of Scalpellum and Ibla to be sexually pure, Gruvel at a later date (1899) claimed to detect rudimentary ovaries in the peduncle of the male *Scalpellum peronii*. Dr. Stewart fails to find in *S. squamuliferum*, and also in a specimen of *S. peronii* itself, any cells that can be regarded as ova, and his descriptions suggest the probability of Gruvel's "cellules ovariennes non développées" being, in truth, large cement-gland cells. Dr. Stewart has also established the absence of any trace of a testis in the female *Ibla cumingii*. His work therefore confirms Darwin's distinction of truly unisexual forms, hermaphrodite forms, and pure dwarf-males among the barnacles.

A lengthy paper in Russian by Mr. S. Kostytschew, dealing with respiration phenomena in plants, is published in the botanical section (No. 1) of "Travaux de la Société Impériale des naturalistes de St. Pétersbourg" (vol. xlii.). From his experiments and conclusions derived therefrom

the author constructs the following theory:—There are two distinct processes to be considered in respiration. On one hand, there is absorption of oxygen leading to the formation of certain oxidising substances, notably peroxides, and on the other, decomposition of sugar by a ferment. The immediate products of fermentation may give rise to alcohol, or, under the action of peroxides, may be fully oxidised to carbon dioxide and water.

THE administration report for 1909 of the Ceylon Botanic Garden, prepared by the acting director, Mr. R. H. Lock, together with the supplemental report by other officers, has recently come to hand. Reference is made to the importation of agricultural machinery and tools, not only for planters' estates, but also for the rice lands cultivated by natives. The shot-hole borer, *Xyleborus fornicatus*, a pest on tea bushes, has engaged the attention of the entomologist, Mr. E. E. Green. The historic scourge of the coffee plant, the green bug, *Lecanium viride*, was reported from one district as another pest on tea, and a slug, *Mariaella dussumieri*, was notified as a destructive feeder on young rubber plants. The curator records the first flowering of the apocynaceous shrub *Stemmadenia bella*, and the planting of an avenue of the beautiful pink-flowered variety of *Lagerstroemia Flos-reginae*.

AN important and very useful contribution to hepaticology is provided by Mr. S. M. Macvicar in an enumeration and account of the distribution of liverworts in Scotland, which has been published as the twentieth volume of the Transactions and Records of the Botanical Society of Edinburgh. The compilation of localities and collectors for each species is in itself a formidable task, even when assisted by the cooperation of correspondents. In addition, the author has added to the Scotch records many more new species than any other collector; *Aneura incurvata, Adelanthus decipiens, Acrobollus wilsonii*, and *Calypogeia succica* are four out of several species found as yet by Mr. Macvicar alone. The floristic sketch of the seven botanical provinces contains many interesting details. Considered from an ecological point of view, hepatici become dominant on some of the higher mountain tops, where a Marsupella-Gynomitrium association is often developed. The coterie of Atlantic species is the most important and remarkable, as some of them would be classed as subtropical and do not occur otherwise in Europe.

A PAPER on fungous root tubercles, communicated by Mr. E. G. Arzberger to the twenty-first report of the Missouri Botanic Garden, deals with conditions examined in *Ceanothus americanus, Elaeagnus argentea*, and *Myrica cerifera*; at the same time it is stated that apparently all species of Ceanothus and Myrica possess them to some extent. The course of events was found to be very similar for Ceanothus and Elæagnus. The fungus enters a young root, and in consequence a tubercle is formed; hypertrophy leads to the development of a large cortex in which the fungal mycelium ramifies; the nuclei of the invaded cortical cells increase abnormally; then the fungus forms vesicles, regarded by the author as sporangia, and absorbs nucleus and cytoplasm of the host cell; subsequently the fungal cells disappear. In the case of Myrica there is no tendency to break up the contents of the vesicular structures, and the form of the fungus indicates that it belongs to the genus Actinomyces.

BESIDES the vast store of archæological information which Dr. M. Aurel Stein brought back from Chinese Turkestan and Western Kansu, he and his assistants from the Survey of India carried out a very large amount of careful topographical surveying, which very greatly improves the maps of that region. Plane-table surveys were carried on continuously during the journeys, and these were controlled by astronomical observations for latitude made at seventy-two stations, and by others made during a previous journey in 1900–1. From this material ninety-four sheets are being prepared by the Survey of India on the scale of 1 : 253,440, and will be published in the form of an atlas to accompany the detailed report on the scientific results of Dr. Stein's last journey. In the meantime reduced copies have been published by the Royal Geographical Society in the Journal for March. The whole area from Kashgar to Kan-Chou (long. 75°–101°), including the Takla Makan desert and the mountains bounding it, is plotted on the scale of 1 : 3,000,000. Other maps on the scale of 1 : 1,000,000 show the Kun-Lun range on the frontier of Kashmir, and Western and Central Nan-Shan to the eastward. On all these maps, heights which have been determined by triangulation, or by barometric or clinometric observations, are shown, names have been carefully revised, and the areas occupied by cultivation, scrub or jungle, and desert have been distinguished. The whole forms a most valuable addition to Asiatic cartography.

THE monthly meteorological charts for May issued by the U.S. Weather Bureau for the oceans and for the Great Lakes of North America have been received. Among the various data, in addition to the usual mean values, we may mention an article (on the back of the charts) entitled "Weather Lore of the Sea," which includes a large collection of proverbs. These are not given as unfailing signs of coming weather; in fact, it is pointed out that for some, depending on celestial bodies, such as moon and stars, careful records fail to show the slightest influence, but the mariner may find it interesting to verify others at his convenience. The Deutsche Seewarte also makes good use of the space available at the back of such charts. The North Atlantic chart for April contains a detailed account of the quick voyage of the sailing ship *Potosi* to the west coast of South America and back, together with useful remarks as to the course and the advantage taken of actual and average weather conditions.

WHILE the reports published in NATURE furnish an indication of the papers read before the London Mathematical Society, considerable interest attaches to the annual volume in which these papers are published, as affording a survey of the year's work. The Proceedings of the London Mathematical Society for 1910 (London, Francis Hodgson, 1910) shows the same high standard that has been maintained in previous years, and contains thirty papers, notable among which are five important contributions to analysis by Dr. W. H. Young, F.R.S., and papers by Bateman, Hardy, Dixon, Hobson, Lamb, Watson, and others, altogether twenty mathematicians having contributed to the present volume. In applied mathematics we have papers on electrodynamical questions by Bateman, Cunningham, Hassé, and Larmor, on heat by Carslaw, on diffraction by Lamb, and on attractions by Leathem. The importance of maintaining and further stimulating interest in these proceedings will be evident when we compare the output of English mathematical original work with what is being accomplished elsewhere, particularly in America. We have, in addition to the present "Proceedings," our "Quarterly" and our "Messenger," but if a quantitative test is of any value, the American Society's Bulletin and Transactions,

the American Journal and the Annals certainly have the lead. As regards quality, a comparison is not so easily made. In America groups are now receiving most attention; in the present volume analysis largely preponderates.

According to a copy of a paper in the Bulletin of the Academy of Sciences of Cracow which has reached us, M. H. Merczyng has succeeded in measuring the refractive indices of water and alcohol for electrical waves of 4·5 and 3·5 centimetres, produced by means of a Righi oscillator working in petroleum. The rays sent out by the oscillator are rendered parallel by passing through a spherical flask filled with petroleum, and then fall at an angle of about 40° on the surface of the liquid. The reflected beam is received by a parabolic mirror, which concentrates it on to a thermo-junction. From the angle of incidence and the ratio of the intensities of the reflected and incident beams, the refractive index of the liquid is calculated. The wave lengths are measured by the Fresnel double mirror method. The results obtained, when compared with the known results for longer waves, show that in both cases the region in the neighbourhood of 4 centimetres is one of anomalous dispersion, the refractive indices increasing as the wave-length increases.

Messrs. E. R. Norman and Co., 26 Great George Street, Leeds, have issued a pamphlet describing the Sytam system of making notes and filing papers. The system consists of methods of binding together loose sheets of paper which can be readily introduced or removed or changed in position, forming a compact book. There are four different kinds of mechanism suitable for binding together sheets of various sizes, which range from $3 \times 2\frac{1}{16}$ to $13\frac{1}{2} \times 9\frac{1}{2}$ inches. The system appears to be quite practical and easy of application; we have seen a large ledger in which sheets are arranged for the D schedule (chemistry) of the International Catalogue, the names of the sections of the schedule being indicated by projecting tabs on the edges of the sheets, which renders reference very easy.

"Remarkable Eclipses" and "Remarkable Comets," both by Mr. W. T. Lynn, have just been issued in their eleventh and fifteenth editions, respectively, by Messrs. Samuel Bagster and Sons, Ltd. Both have been brought right up to date, and the most remarkable feature of each is the enormous amount of information compressed within so small a compass and sold at the low price of 6*d*. each net. The former volume includes notes on the most remarkable eclipses of the sun since 1063 B.C., and of the moon since 721 B.C., while the second briefly describes all the remarkable comets of which history speaks, even though it be with far-off whispers. An excellent drawing of Halley's comet, as seen by Miss E. M. Phillips at Barbados on May 17, 1910, is an additional feature, new in this edition.

The April issue of Mr. C. Baker's quarterly classified list of second-hand instruments contains a description of more than 1500 pieces of scientific apparatus for sale or hire at Mr. Baker's second-hand department, 244 High Holborn, London.

In Mr. E. P. Stebbing's paper on "Tree Planting in Towns," on p. 197, col. 1, of Nature of April 6, the word "Etna" should have been "Everest." Mr. Stebbing asks us to correct this error, which was made by his typist, and was overlooked by him in the proof of the paper submitted to him.

OUR ASTRONOMICAL COLUMN.

April Meteors.—Mr. W. F. Denning writes:—"The April meteoric shower will occur this year when there will be little moonlight. With clear skies it ought to be very satisfactorily observed, but the character of its return cannot be predicted.

"On April 19, 1803, there was a fine display, but it has not returned in the same abundance during the 108 years which have clapsed since the date alluded to. There is no reason to anticipate a brilliant exhibition this year, but the sky should be vigilantly watched on the nights of April 20, 21, and 22, so that if the shower actively returns it may be suitably recorded. It is often of short duration, and true Lyrids are rarely, if ever, observed before April 17 or after April 24.

"From observations made at Bristol since 1873, I certainly believe that the radiant point is liable to the same easterly motion as that which affects the emanating centre of the Perseids. But the April stream supplies so few meteors, except on the date of maximum, that it is extremely difficult to get the precise position of the radiant point on the 17th and 18th, and 23rd and 24th. Observers would do well to gather as many apparent paths as possible on the nights just named. Records of meteors obtained at two stations would be specially valuable as serving to indicate the point of radiation accurately. On April 18, 1901, 13h. 19m., a bright Lyrid was recorded by Prof. Herschel at Slough, and by the writer at Bristol, and the radiant was indicated at $266° + 33°$. This object afforded evidence that the Lyrid focus is a changeable one, for its centre is at $270° + 32°$ on April 20. Additional observations of similar character would supply valuable details bearing on an interesting feature of the display."

The Spectrum of Nova Lacertæ.—Spectrograms of Nova Lacertæ were secured at the Potsdam Observatory on January 6, 7, 8, and 23, and are described by Prof. Münch in No. 4490 of the *Astronomische Nachrichten*. The wave-lengths were determined by taking the mean measured wave-lengths of the hydrogen lines as normal, and then interpolating the other measures. Naturally, no rigid accuracy is claimed for the values as being absolute, but the table is a useful record of the lines seen and of their various intensities and characters. On January 7 $H\gamma$ and $H\delta$ were sharply defined on the red side, but diffuse on their more refrangible edges, where they were accompanied by broad absorption bands: the maximum intensity lay on the red side of each line; on the other hand, $H\epsilon$ and $H\zeta$ were equally sharp on both sides. The usual decrease in the intensity of the continuous spectrum took place, and on January 23 it was much fainter than on January 7. Prof. Münch discusses the intensity curve of the nova spectrum, and by a comparison of the distribution of energy therein shown with that given by several stars of the A type, he derives an energy curve for the nova.

The Different Quality of the Light Reflected from Various Parts of the Lunar Surface.—It will be remembered that Prof. R. W. Wood found recently that, when photographed in ultra-violet light, various features on the moon presented different appearances from those presented on ordinary photographs.

Working at the Charlottenburg Technischen Hochschule, Herren A. Miethe and B. Seegert have carried the investigation a step further by using two screens in connection with a reflector, one of which transmitted light of wave-lengths 360–330 $\mu\mu$, the other light of wave-lengths 700–600 $\mu\mu$. A comparison of the plates so obtained shows remarkable differences of illumination, especially on some of the surfaces of the *maria*. The higher parts of the lunar surface, especially in the region of the south pole and about the ring mountains of Copernicus, reflect hardly any ultra-violet light, while the north polar regions reflect a great deal. By projecting the two photographs through complementary screens, the differentiation of colour is brought out remarkably, the Sinus Roris and Mare Nubium showing remarkable variations (*Astronomische Nachrichten*, No. 4489).

The Pyrheliometric Scale.—A paper with important bearing on the question of the value of the solar constant is published by Messrs. Abbot and Aldrich in No. 3, vol.

xxxiii., of *The Astrophysical Journal.* Feeling dissatisfied with the Crova alcohol actinometer obtained in 1902, Mr. Abbot conceived the idea of constructing a new form of pyrheliometer. This consists of a double walled, large test-tube blackened within, with a stream of water circulating between the double walls and absorbing the heat collected inside the chamber. The sun's rays shine into this chamber through a measured orifice, and the heat collected by the water is measured by a system of platinum wires forming a resistance thermometer.

Test experiments with electrically heated coils, in which the heat could be measured with great accuracy, have shown that the water system collects all the heat introduced within 1 per cent., and that the solar heat can be collected and measured to within 0·2 per cent. Thus the scale of the solar-constant observations of the Astrophysical Observatory is reduced to the absolute scale of calories (15° C.) per square centimetre per minute within a probable error of 0·2 per cent., an accuracy hitherto not attained.

DOUBLE-STAR OBSERVATIONS. Circular No. 6 of the Transvaal Observatory contains a list of about 350 double stars discovered with the 9-inch Grubb refractor of the observatory during 1910. Mr. Innes directs attention to the common statement that the southern heavens offer a practically unexplored field to the would-be double-star discoverer, and shows that this is by no means the case. The circular also contains a list of double stars discovered by Mr. Ward at Wanganui, New Zealand. The list contained observations of 212 stars, but has been revised, and in some cases the observations confirmed, by Mr. Innes.

Nos. 4486 and 4488 of the *Astronomische Nachrichten* also contain series of double-star measures, the former by Herr J. Voûte at the Leyden Observatory, the second a longer list of micrometer measures by Prof. H. E. Lau at Copenhagen.

MICROMETRICAL MEASUREMENTS OF NEBULÆ.—A useful catalogue of nebulæ lying south of the equator is published as No. 17 of the Publications of the Cincinnati Observatory. In the preface Prof. Porter explains that when the 16-inch Clark refractor was ready for work at the end of 1904 it was decided to observe those nebulæ of Dreyer's N.G.C. which have southern declinations, and the work has been carried on since. There was no idea of discovering new objects, but seventeen were found, of which nine appear certainly to be novæ. The catalogue includes the positions of 669 objects, with the micrometrical measures of them and of the companion stars.

THE MOTION OF CERTAIN STARS IN SPACE.—As an extract from the *Bulletin Astronomique*, we have received a paper in which Prof. Stroobant discusses the question of the sun being a member of a group of stars having a common motion through space. In the result, he finds a fairly strong indication that the sun does belong to such a system, which also comprises the stars α Cassiopeiæ, β Persei, α Persei, α Scorpionis, γ Cygni, and ϵ and α Pegasi.

THE COMPOSITION OF THE GASES CAUSED BY BLASTING IN MINES.[1]

THE report before us was drawn up for the Government of Western Australia by Mr. E. A. Mann, the Chief Inspector of Explosives. The importance of investigations on the subject of the composition of gases caused by blasting in mines cannot be overestimated, since, hand in hand with the safety in actual use of blasting explosives, there is the possibility of accidents arising from the products of the explosion accumulating in badly ventilated headings. This risk has been recognised by several Governments, and investigations instituted. In the present case a most valuable and suggestive report is the outcome.

Nitroglycerine is the only largely employed explosive which contains more than sufficient oxygen for its complete combustion, and on firing should therefore yield only carbon dioxide, nitrogen, water vapour, and an excess of oxygen. The explosives investigated were mainly nitroglycerin explosives: blasting gelatin (nitroglycerin with approximately 10 per cent. soluble nitrocellulose), gelatin dynamite, and gelignite, both of which contain wood meal and potassium nitrate. Generally speaking, the former contains a slight deficiency of oxygen, whilst the latter two an excess.

The gases produced on firing under actual working conditions were collected by Mr. Mann, who wore for the purpose a Fleuss oxygen apparatus. In all 131 entries were made into the dangerous gases, and analysis invariably showed that carbon monoxide, which is so highly poisonous, was produced, together with small quantities of oxides of nitrogen, dangerous by reason of their physiological activity.

An important ratio obtained is that between $CO : CO_2$, which is a fair measure of the relative dangers of gas-poisoning with the different explosives. The highest is found with blasting gelatin (1 : 6·5), a general average for all the explosives being about 1 : 13. It is well known that pressure on firing exercises an enormous difference in the distribution of oxygen to form carbon dioxide or monoxide, high pressures increasing the CO_2, and this has an important bearing in practice. If the explosives mentioned are fired in a bomb, the maximum oxidation results, since maximum pressure is attained. In a rock, the greater the resistance, either from its character or the position of the charge, the lower should be the ratio $CO : CO_2$. The ideal condition would be where the rock only gives just when the maximum pressure is reached; but this is a condition impossible to realise in practice, so that holes are invariably overcharged, *i.e.* the rock is blown out before oxidation has been completed, hence the production of carbon monoxide.

Two very important points are brought out, first, the influence of the paper wrapper of the cartridge, which gives a deficiency of oxygen on the whole charge. Comparative tests with and without wrappers show that in the case of gelignite the ratio $CO : CO_2$ has been reduced from 1 : 16 to 1 : 51, and in the case of blasting gelatin from 1·95 to 1 : 52. Secondly, the influence of the physical condition of the powder; where the most intimate mixture of the ingredients is obtained, there is every chance of oxidation proceeding more rapidly to the maximum actually obtainable before rupture of the rock. Some excellent coloured plates of the microstructure of many of the explosives under polarised light emphasise the frequent heterogeneity of their structure.

The effect of fuse firing as compared with electric firing is carefully considered, and everything is greatly in favour of the electrically fired charge, fuses being responsible for much deleterious gas.

[1] Report on investigations into the Composition of the Gases caused by Blasting in Mines, by E. A. Mann, Chief Inspector of Explosives for Western Australia. (Perth: by authority: Fred. Wm. Simpson, Government printer.)

DRAINAGE AND MALARIA.

IN India, the sanitary expert adviser of the complacent type must either "bend or break" under the weight of official opinion (held as strongly by the youngest Under-Secretary as the veteran Financial Member) that the Sanitary Department must be classed financially as "unproductive," and must therefore be, in its representations involving expense, tactfully unobtrusive. Hence, possibly, the unconscious evolution of the policy of "quinine prophylaxis," which would relieve the Government of India from applications for loans and "free grants" for radical anti-malarial measures, such as drainage works, requiring the sinking of capital, and would throw upon the inhabitants of malarious areas (who are notoriously impecunious as a sequence of disability to labour) the onus of purchasing an expensive drug—through an indefinite number of years.

In connection with the letter in NATURE of February 9 by Dr. Bentley—one of the small circle of supporters of this policy—and the reply thereto by Dr. Malcolm Watson, there is now available a record[1] of facts at issue, which will enable those interested in a question of much import-

[1] "The Prevention of Malaria in the Federated Malay States." By Dr. Malcolm Watson, with a preface by Prof. Ronald Ross, C.B., F.R.S. Pp. 139. (Liverpool: School of Tropical Medicine, 1911). Price 7s. 6d.

ance to communities of tropical countries, and, consequently, of our national commerce, to draw their own conclusions. Readers of this very valuable statement of work fulfilled and observations made by a keen and practical sanitarian will find no difficulty in recognising that the "marked rise of subsoil water," which coincided with the increased incidence of malarial fevers, was the "special influence" at work in Klang; that this occurred in an already malarious town in constant communication with surrounding malarious areas, with the result that transfer of infected inhabitants to the swamps of Port Swettenham found ready-made conditions for the continuance, if not aggravation, of epidemic malaria; and, consequently, the increased incidence was not due to the ephemeral effect of importation of ill-fed coolies, but primarily to local physical conditions remediable, and actually remedied, by judicious engineering operations.

This record shows that in Klang and Port Swettenham the abolition of pools by drainage (without the aid of quinine prophylaxis in the former case, even as a temporary measure) rapidly rendered possible commercial undertakings of great monetary value, which had been interrupted on account of disability of the available labour; that whilst there obviously is no desire on the part of the author to belittle the utility of quinine prophylaxis, he found that to secure maintenance of coolie labour upon estates the daily consumption of quinine necessary, under careful supervision of the subjects, was in quantities that a free Indian population could neither afford nor be persuaded to take; that the survivors of this temporising effort remained at the end of two and three years of daily administration of quinine the bearers of malaria parasites, and therefore were a danger to themselves and their neighbours; and that by effectual removal of surplus moisture of the soil, there is excluded fear of epidemic malaria following the introduction of malaria-parasite bearers—an "influence" which, in the absence of drainage, certainly cannot be ignored. Nor is it only in Klang and Swettenham that these results have been illustrated, but in several planting estates, where previously the loss by coolie labour paid for, but unavailable from sickness and death, was of grave moment; here also has been gathered valuable information as to the necessary radius of protective zones.

Seeing that, in accordance with the policy of the sanitary expert advisers of the Government of India, the Punjab Government has recently inaugurated an anti-malarial campaign by purchasing *a ton of quinine*, it is not likely that the amount of this drug found necessary by Dr. Malcolm Watson for the mitigation—not eradication—of malaria in a free population will surprise them. The Government of Eastern Bengal and Assam has, however, adopted a method more likely to be grasped by the people; whilst assigning drug prophylaxis to the millennium, it, in the meantime, asks its malaria-stricken populations to indulge in the so-called quinine "treatments" at three annas *per* head *per* attack—or a sum exceeding the total average annual taxation *per* head on account of district boards serving under it.[1] In this case, presuming two attacks *per annum per* head in a population of 15,421, there would be spent (in one sense) "unproductively" against a preventable disease sufficient to meet the sinking fund and interest, by annual instalments, of a loan for thirty years of one lakh of rupees. Yet the chances are that were a lakh sunk in any well-designed anti-malarial drainage scheme, there would be illustrated the truism that "prevention is better than cure"—both for commercial and humanitarian reasons.

W. G. King.

SOME PAPERS ON INVERTEBRATES.

In the report of the Government entomologist, issued by the U.S. Department of Agriculture, for 1910, will be found a full account of the work accomplished during the year under review, and a scheme for future work. Certain points connected with the life-history of the brown-tail and the gipsy moth engaged attention during the year, more especially the presence of isolated colonies of the latter in woodland districts. As the result of these investigations, it was found that newly hatched caterpillars may be carried by wind to a distance of nearly 2000 feet. Of late years the Argentine ant has caused such damage to orange-plantations in Louisiana that several have been abandoned, but it is believed that a practical method of keeping this pest in check has now been discovered.

New species of artificially reared ichneumon-flies and new South American parasitic Hymenoptera form the subject of two articles, respectively by Mr. H. E. Viereck and Mr. J. C. Crawford, in the Proc. U.S. Nat. Mus. (Nos. 1789 and 1786).

It seems somewhat strange that it should be left to a Japanese naturalist to describe new cicadas from Europe and the Mediterranean countries. Nevertheless, such has been the case, and in the Journal of the College of Science of Tokio University, vol. xxvii., art. 18, Prof. S. Matsumura, who writes in German, concludes his paper on this subject, describing as new no fewer than forty-two species, together with two new genera.

In *Naturwissenschaftliche Wochenschrift* of February 5 Prof. J. Meisenheimer records the results of experiments for testing the power of regenerating their wings in insects, the moth *Lymantria dispar* being the subject of these experiments. The first traces of the wings occur as minute outgrowths from the sides of the last two limb-bearing segments of the caterpillar, and in the large series of specimens submitted to experiment these were cut away on one side. In a few instances the wings on the injured side were represented by mere knobs, but in most cases more or less well-developed wings were grown, although very generally smaller than the normal ones. Sometimes one wing on this side may be fairly well grown, and the other quite small. Details on this point, and also in regard to variation in the colour-pattern, are given in the paper.

The Entomologist's Monthly Magazine for March contains two papers—one, with a coloured plate, by Miss E. M. Alderson, and the other, by Mr. E. A. Atmore—on the beautiful little lace-wing fly, *Chrysopa dorsalis*, first added to the British list in 1900 on the evidence of specimens taken in Surrey, but subsequently found in Norfolk. The species, which frequents the needles of Scots fir, has been bred in confinement by Miss Alderson.

A synopsis of the true crabs inhabiting Monterey Bay, California, forms the subject of an article by Mr. F. M. Weymouth, issued as No. 4 of the Leland Stanford Junior University Publications. This communication, which is very fully illustrated, is to form one of a series of papers of similar scope dealing with the fauna of Monterey Bay for the purpose of rendering the local forms of invertebrates easily identifiable by the students at the Marine Biological Laboratory of the University.

The structural arrangements in the females of the decapod crustaceans of the family Peneidæ for receiving and storing the sperm are described and illustrated by Mr. E. A. Andrews in No. 1791 of the Proc. U.S. Nat. Mus. The females of this family present the comparatively rare feature of having special receptacles, or spermatotheca, for this purpose on the ventral aspect of the body, and the different degrees of complexity of these structures in the various species and genera are illustrated by sections. The alleged existence of receptacles of the same type in the females of the deep-sea prawns of the group Eryonidæ is considered by the author to be improbable.

North American parasitic copepods of the family Ergasilidæ form the subject of No. 1788 of the same serial. The family, according to Mr. C. B. Wilson, includes ten genera, three of which are described for the first time, while the definition of a fourth is revised. All its members live almost entirely on the gill-filaments or within the gill-cavities of fishes, but whereas adult females become more or less fixed, the males remain free-swimmers, and in the case of one genus do not appear to be parasitic at all. Hence males are much scarcer in collections than females, and after the breeding season can only be taken in the tow. The genera may be arranged in the three subfamilies, of which one is typically fresh water, while the other two are marine.

No. 1783 of the Proc. U.S. Nat. Mus. is devoted to the ninth portion of Mr. C. B. Wilson's memoir on North American parasitic copepods, the author dealing in this

[1] In Italy, under laws passed 1901-03, the poor and all workers have the right to receive quinine for treatment *and* prophylaxis gratuitously from the State.

instance with the family Lernæopodidæ. Special attention has been directed to the development of certain members of the family, the new facts being recorded in a summary at the end of the paper, which is too long and too technical for quotation in this place.

In No. 1785 of the serial just quoted, Mr. P. Bartsch describes several new species of molluscs of the family Vitrinellidæ from the Pacific coast of North and Central America, with illustrations of the shells.

The cyclostomatous polyzoans of the same coast are discussed by Miss A. Robertson in vol. vi., No. 12, of the University of California Zoological Publications, this communication being the third of the series. In addition to the description of new species, the author directs special attention to the ovicel, with particular reference to the investigations of Dr. S. F. Harmer.

A number of polyzoans ranging from the Ordovician to the Cretaceous, and common to Europe and North America, many of which have been included by previous writers in Stomatopora, are referred by Mr. R. S. Bassler in No. 1797 of the Proc. U.S. Nat. Mus. to a new genus under the name of Corynotrypha, for the distinctive characters of which those interested in the subject must consult the original paper.

In the Proceedings of the Royal Irish Academy, vol. xxix. (B), No. 3, Mr. A. W. Stelfox gives an annotated distributional list of the land and fresh-water molluscs of Ireland. The author acknowledges his indebtedness to Dr. Scharff in working out the fauna generally, and to Mr. B. B. Woodward for the discrimination of the species of Pisidium. Fourteen land and fifteen fresh-water species inhabiting Great Britain have not yet been recorded from Ireland, and since most of these belong to the central European fauna, there is considerable probability that they never reached the western island. On the other hand, a Hygromia which apparently belongs to the Cornish outlier of the Lusitanian fauna may turn up on the east coast of Ireland, while search for *Limax tenellus* should be made in the northern and north-western districts.

The slugs of Natal form the subject of a paper, by Mr. W. E. Collinge, published in the Annals of the Natal Museum, vol. ii., part ii. These are referable to fifteen species, arranged in six families, of which the Aperaidæ, as represented by the exclusively South African genus Apera, is new. Of the five species of this remarkable genus, which has hitherto been included in the Testacellidæ, three are found in Natal. The genus is believed by the author to represent a very primitive type, such resemblances as it shows to the Testacellidæ being probably due to parallelism. It was originally described, in 1879, as Chlamydephorus, a name which clashes with the mammalian Chlamydophorus. The author states that the latter name was given by Agassiz in 1844, but it was really proposed in 1824 by Harlan, in the form of Chlamyphorus, and this difference in the original may give rise to the question whether it really preoccupies Binney's Chlamydephorus.

No. 5 of the fifth volume of *The Philippine Journal of Science* is devoted to a description, by Mr. L. E. Griffin, of a new species of the protozoan genus Euplotes, for which the name *Eu. worcesteri* is proposed. The type-specimen was found in 1909 in water brought to the Manila Laboratory from the neighbouring bay. The species, of which exquisite illustrations are given in the plates accompanying the memoir, is very closely related to *Eu. vannus*.

A new generic type of crinoid, *Thalassocrinus pontifer*, from the Philippines is described by Mr. A. H. Clark in No. 1793 of the Proc. U.S. Nat. Mus. It is a stalked form referable to the family Hyocrinidæ, with its nearest relationship, apparently, to Gephyrocrinus.

R. L.

PAPERS ON SYSTEMATIC BOTANY.

AN important feature in the revision prepared by Dr. C. B. Robinson of Philippine Urticaceæ, is the discussion of generic limits and relationships. A new genus, Elatostematoides, is proposed for certain species previously referred to Elatostema or Pellionia, and another genus, Astrothalamus, allied to Maoutia. Under Laportea, a genus of notoriety on account of its stinging hairs, it is mentioned that the hairs are siliceous, and may contain formic and acetic acids; also that prompt relief is afforded by ammonia or carbonate of soda. Many new species are differentiated, notably nine for Laportea and twenty for Elatostema. The first part only of the article appears in the concluding number of the fifth botanical volume of *The Philippine Journal of Science*.

The second number of the current volume of *The Kew Bulletin* contains the diagnoses of thirty new African species, chiefly under the genera Protea, Sorocephalus, Loranthus, and Erythrococca, a note by Mr. G. Massee on a lilac disease, and an article on the beechwood industry of the Chilterns by Mr. W. Dallimore. The lilac disease caused by the hyphomycete, *Helminthosporium syringae*, shows first as a brown stain on either side of the leaf; the stained area extends and darkens, and olive-brown patches of fruit appear; later on, spores are formed in great abundance. Spraying with a solution of potassium sulphide in an early stage serves to check the disease. Mr. Dallimore deals more particularly with the chair-making industry centred in High Wycombe, and the brush-making industry of Chesham.

Recognising the difficulties of delineating the various species of Castilla (Castilloa), Mr. H. F. Pittier designates his careful and well-illustrated revision of the genus in the Contributions from the United States National Herbarium (vol. xiii., No. 7) a preliminary treatment, although his conclusions are based largely upon experience in the field. Ten species are distinguished, of which four from South America are placed in a separate group, while the second consists of Central American species, differing more or less from *Castilloa elastica*. The practical object of the publication is to make known the diversity of species that may be under cultivation as *C. elastica*. It is noted that *C. nicoyensis* is a good latex producer, and that *C. costaricana* is tapped by the native collectors.

A catalogue of non-herbaceous phanerogams cultivated in the Royal Botanic Garden, Calcutta, published as vol. v., No. 1, of the Records of the Botanical Survey of India, is not a mere list of species, but is designed to identify and locate every tree or shrub growing there. For this purpose the plan of the garden is divided into squares distinguished by letters and figures, and in addition each plant receives and is labelled with an individual number; thus one specimen of *Schleichera trijuga* is listed as O 10, 1641. At points corresponding to the intersection of lines posts are inserted in the garden to locate the squares. Further, a record of source and history is tabulated for each individual plant to be registered in a filed system, and special sheets have been designed for keeping note of seeds. The present index part will be supplemented by a systematic part furnishing the "stock account" of the garden.

REPORTS ON GLACIOLOGY.[1]

(1) STUDENTS of glaciology owe a debt of gratitude to M. Rabot, because information on this subject is scattered over a wide field and in unexpected places. To collect that contained in the present number of the *Revue* must have been a heavy task, and its value is increased by a careful classification. The earlier sections deal with matters such as precipitation, its form and relation to altitude, the rate at which snow melts, avalanches and their consequences, the formation of glaciers, their structures, their dates of movement, and their erosive effects, in regard to which last diverse opinions are quoted. If we can believe Prof. Hans Hess, a glacier deepens its bed by 1 metre in from thirty to fifty years, or, in other words, the erosive power of ice is at least ten times as great as that of running water. Figures are cited to support this conclusion, but a tolerable familiarity with glaciers and their works, for at least that time, leads us to suspect there is something wrong with the figures or the observations.

[1] (1) Revue de Glaciologie. No. 3 (avril 1903–1er janvier 1907). By Charles Rabot (Mémoires de la Société Fribourgeoise des Sciences Naturelles, vol. v., Band v., Géologie et Géographie). Pp. 344+30 figures. (Fribourg, Suisse, 1909.) Price 6 francs.
(2) Les Variations périodiques des Glaciers. XVme Rapport, 1909. Rédigé par Dr. E. Brückner et E. Muret. Extrait des Annales de Glaciologie, t. v. Janvier, 1911. Pp. 177—202. (Berlin: Borntrager Frères, 1911.)

Many as are the important facts from almost every part of the globe which the present number contains, it must suffice to notice only the chapter on the causes of variation in glaciers. The data there cited show that, at any rate under certain conditions, the winds are factors, especially in the removal of snow, more potent than has been hitherto supposed. In regions of low temperature, but of high winds, these drive the snow before them, like sand in the desert, and thus check the formation of glaciers. The volume of an ice-stream, speaking in general terms, is a function of two variables, the one alimentation, the other ablation. Hitherto the effect of the latter has been underestimated, the advance or retreat of a glacier having been supposed to be mainly dependent on the amount of the snow which falls on the upper part of its basin.

M. Rabot classifies the years from 1826 to 1906 in groups, according as the rainfall or the summer temperature at Geneva was above or below the average, and states that in the former case the Swiss glaciers, as a rule, retreated, and in the latter advanced. Similar, though less precise, evidence is obtained from other regions, so that it is very probable, to quote Prof. Forel's words, that the variations in summer temperature produce more effects upon glaciers than has hitherto been supposed. On the latter subject, and especially on the changes during the last few years, a very large amount of information is given. In short, its editor has made the *Revue* indispensable to all interested in the study of glaciers.

(2) The Commission Internationale des Glaciers decided at Stockholm last August that this report should appear at an earlier date. Hence a supplement will be necessary to contain documents which have not yet been received. Still, this number includes Europe, with Russian Asia and the United States of North America. The results show a general but slow decrease of the glaciers. To this rule there are local exceptions, which, however, are few except in Scandinavia; and even here they are in a minority. It is suggested that in Norway changes in the humidity of the air, due to the shifting of ocean currents, produce more effect on climate and glacial oscillation than those in temperature. Some sets of observations in the French Alps are more than usually systematic, for the investigators take account of avalanches and calculate the rate of flow and of ablation at the surface of glaciers between two stations. They note that 683 out of 740 avalanches followed a customary course, and estimate the amount of débris brought down by them at 2243 cubic metres. Altogether the number contains not a little interesting information.

THE ASSOCIATION OF ECONOMIC BIOLOGISTS.

THE tenth general meeting was held in the University of Birmingham, under the presidency of Prof. G. H. Carpenter, on April 6 and 7. There was a good attendance.

The president communicated a paper on some dipterous larvæ which last year caused considerable damage to crops of swedes near Dundalk, Ireland. These belonged to an apparently new species of gall-midge and to *Scaptomyza flaveola*. In connection with this species, several points of interest in the structure of the larva were demonstrated by means of photographs and drawings shown in the lantern.

Mr. H. Maxwell Lefroy, in a very interesting address, spoke on the training of economic entomologists. Not the least difficulty in making economic zoologists in England was the preponderance of the academic view and the total absence of the economic view based on experience. He pointed out that, in addition to a training in zoology, botany, and chemistry, a course in agriculture should be taken, and a knowledge of field work in entomology was useful.

Mr. Walter E. Collinge read a paper on house-flies and public health, in which it was pointed out that there was now no longer any doubt that cholera and typhoid fever were both spread by these insects, and that there was accumulating evidence that infantile diarrhœa, dysentery, and tuberculosis were also. Mr. Collinge contended that a proper system of control and prevention were essential on the part of every corporate body having anything to do with the health of the general public. After briefly referring to the ordinances and regulations in force in other countries, he commented upon the inadequate conditions for the keeping of food in the modern dwelling house, and the necessary regulations for the disposal and storage of manure, &c. In concluding, he pointed out that it remained with the general public to educate the authorities in these and like matters if we have to remove from our midst a danger full of potentialities to ourselves and our children, and detrimental to the public at large.

An interesting discussion on the standardisation of economic nomenclature was opened by Mr. H. Maxwell Lefroy, and a committee was appointed to deal with the matter.

Dr. G. H. Pethybridge gave an account of some recent work on diseases of the potato plant in Ireland, where the potato crop is peculiarly liable to suffer. Great advances have been made in recent years in checking the ravages of different diseases, but there are still many that have not yielded to treatment. A considerable amount of attention has been given by the author to these, and the results were very fully described and illustrated.

Mr. W. B. Grove described four little known British fungi, viz. *Mucor spinosus*, *Monilia lupuli*, n.sp., long known to brewers as occurring on spent hops, but hitherto undescribed. *Rhopalocystis nigra* was a new name proposed for *Aspergillus niger*, and *Hormodendron cladosporoides*, a species often confounded with *Cladosporium herbarum*.

Mr. Walter E. Collinge directed attention to the extremely serious nature of the plague of eelworms and white worms which are at present attacking different crops throughout the country, and to the scanty nature of our knowledge of their life-histories and bionomics. Dr. J. H. Priestley initiated a discussion on the systematic recording of diseases of economic plants. The occurrence of the beetle *Necrobia rufipes* in cotton bales formed the subject of an interesting communication by Mr. Joseph Mangan. Mr. G. E. Johnson demonstrated some stages in the life of the nematode living in the nephridia of the earthworm. The association accepted the invitation of Prof. Carpenter to meet in Dublin in 1912 at a date to be fixed later.

THE CONSERVATION OF OUR NATIONAL WATER RESOURCES.

AN interesting paper on the above subject was read by Mr. W. R. Baldwin-Wiseman before the Surveyors' Institution on January 27. This may be considered as the complement to the paper read by the author before the Royal Statistical Society in 1909 on the increase in the national consumption of water. In the earlier paper Mr. Baldwin-Wiseman dealt with the enormous increase in the consumption of water, and the reasons for such increase, and he referred very shortly to the necessity for the creation of a central authority which should be charged with the duty of water conservancy in its widest application, and, for that purpose, should engage in a close and exact study of the water resources of the country. He now deals with some of the methods adopted by different countries to conserve and use in a systematic way the water which they possess. It is rightly pointed out that the particular use of water to which greatest attention is required varies in different countries. In the United Kingdom the water supply for domestic purposes and trade uses is all-important, and with it must be coupled the prevention of stream pollution. In Italy, Switzerland, Norway, and Canada water-power development is predominant. In Egypt, India, parts of Australia, and certain regions of the United States and Canada irrigation claims first place. In Germany and Belgium inland navigation is of extreme importance, while Holland devotes attention to drainage and reclamation.

The author's researches as regards what has been done by various countries for the conservation of water for the different purposes mentioned are of a careful and exhaustive character, and it must have taken considerable time and

labour to collect this information. To all those who are engaged in water schemes perusal of the paper cannot fail to be of interest, but it will probably cause disappointment to find how little information as regards water is available in the United Kingdom in comparison with that available in some other countries.

The author concludes his paper by suggested lines of organisation in this country so as to have all matters relating to water administration under one central authority. It will probably take some time before such a complete organisation as is suggested can be attained, but there is no reason why some of the smaller suggestions should not be carried out at once. We feel sure that if the importance of the question were fully brought before the present President of the Local Government Board he would be able with very little expense and without a large supply of red tape to deal quickly with such suggestions as annual returns from all water-supply and sewage-disposal authorities, and the beginning of a hydrographic survey. If a start were once made and the importance of the matter realised, the larger details of organisation would gradually evolve themselves.

The author has added to his paper some tables dealing with the use of water in various countries, and there is also a useful bibliography. M. F.

THE COMPOSITION OF PINE WOOD.

A MONOGRAPH on the "Chemical Composition of Pine-wood," by Prof. Klason, of Stockholm, has been issued by Gebrüder Borntraeger, of Berlin, as the second of a series of "Schriften des Vereins der Zellstoff- und Papier-Chemiker." In addition to the importance of pine-wood as the chief raw material of the paper industry, this particular wood has acquired a special scientific interest from the important colour-reactions in which it has figured as a test material. Thus phloroglucinol imparts a red-violet colour to a pine splinter moistened with hydrochloric acid, aniline sulphate a yellow colour, pyrocatechol and resorcinol a red-violet, pyrogallol a grey-violet, pyrrol and indol a red, phenol a blue, α-naphthol with sulphuric acid a green, hæmatoxylin a violet, naphthylamine hydrochloride a yellow, aminoanthracene hydrochloride a red, phenylhydrazine hydrochloride a yellow, and so forth.

These reactions appear to be characteristic of a substance to which the name of "lignin" has been given; similar reactions are shown by the well-known flavouring substance "vanillin," but this is not present as such in appreciable quantities in pine-wood. Lignin is richer in carbon than cellulose, but contains the same proportion of hydrogen; it differs from cellulose in that it is not dissolved by ammoniacal copper oxide, and gives no blue coloration to zinc chloroiodide, but can be reconverted into cellulose by oxidation, and separated from it by dissolution in alkalis or by the action of sulphites, which appear to convert it into soluble sulphonates. The author has analysed the calcium sulphonate, and attributes to it the formula $C_{40}H_{44}O_{17}S_2Ca$; this corresponds with a composition $C_{40}H_{42}O_{11}$ for lignin itself, but molecular weight determinations give values above 4000. In addition to two molecules of sulphur dioxide, lignin combines with two atoms of iodine, and thus contains three double-bonds in the C_{40} complex; four methoxyl groups are present and one hydroxyl group. The substance is probably a condensation-product of coniferyl alcohol,

$$CH_3O.C_6H_3(OH).CH:CH.CH_2.OH,$$

(a substance which can be oxidised to vanillin), with an oxyconiferyl alcohol in which the substituents are grouped in the same way (1:3:4:5) as in gallic acid, thus

$$2C_{10}H_{12}O_3+2C_{10}H_{12}O_4-3H_2O=C_{40}H_{42}O_{11}.$$

Lignification appears to consist in embedding the pliable cellulose in a hard crust of lignin; by the action of a sulphite the lignin is dissolved out, and the clean cellulose which is left constitutes the paper pulp. The sulphite extracts, from which lignin can easily be recovered, might very possibly prove to be valuable raw material for the manufacture of artificial vanillin. T. M. L.

RECENT ADVANCES IN TURBINES.[1]

ON two previous occasions I have addressed this institution on the steam turbine. At the time of the first lecture, in 1900, the turbine may be described as having been in the "advanced experimental stage." Six years later it was meeting with "general acceptance" in certain fields. To-night I propose to review its progress from 1906 to the present time; but before doing so I shall, with the view of leading up to the subject, and at the risk of some repetition, briefly explain the chief features of interest, and recapitulate some of the earlier steps in its introduction.

The first turbine of which there is any record was made by Hero of Alexandria 2000 years ago, and it is probably obvious to most persons that some power can be obtained from a jet of steam either by the reaction of the jet itself, like a rocket, or by its impact on some kind of paddle-wheel. It is, however, not so obvious that an economical engine could be made on this principle. In the year 1888 Dr. de Laval, of Stockholm, undertook the problem with a considerable measure of success. He caused the steam to issue from a trumpet-shaped jet, so that the energy of expansion might be utilised in giving extra velocity to the steam. Recent experiments have shown that by such a device nearly the whole of the available potential energy in the steam is converted into kinetic energy of velocity in a straight line, the velocity attained into a vacuum being about 43,000 feet per second. Dr. de Laval caused the steam to impinge on a paddle-wheel made of the strongest steel, which was allowed to revolve at the highest speed consistent with safety, for the centrifugal forces are enormous. Unfortunately, materials are not strong enough for the purpose (in the large sizes the speed is nearly half that of a rifle bullet), and the permissible speed of the wheel can only reach to two-thirds of that necessary for good economy, as we shall presently explain.

Dr. de Laval also introduced spiral helical gearing for reducing the enormous speed of his wheel to the ordinary speeds of things to be driven, and we shall allude to this gear later as likely to play a very important part generally in future turbine developments.

In 1884, or four years previously, I dealt with the turbine problem in a different way. It seemed to me that moderate velocities were essential if the turbine motor was to receive general acceptance as a prime mover. I therefore decided to split up the fall in pressure of the steam into small fractional expansions over a large number of turbines in series so that the velocity of the steam nowhere should be great, and consequently, as we shall see later, a moderate speed of turbine suffices for the highest economy. This principle is now universally adopted in all except very small turbines, where economy is of secondary importance. This arrangement of compounding turbines also appeared to me to be surer to give a high efficiency, because the steam was caused to flow in a non-expansive manner through each individual turbine, and consequently in an analogous way to water in water turbines, where high efficiency at that date had been proved. I was also anxious to avoid the well-known cutting action of high-velocity steam on metal.

The close analogy between laws for the flow of steam and water under small differences of pressure have been confirmed by experiment, and the usual formula $=\sqrt{2gh}$, where h is the hydraulic head, gives the velocity of issue from a jet for steam with small heads and also for water, and we shall presently follow this part of the subject further in dealing with the design of turbines.

Having decided on the compound principle, it was necessary to commence with small units at first, and in spite of the compounding the speed of revolutions was still high.

Though, as we have said, the de Laval turbine appeared four years later, the de Laval cream separators were in use prior to 1884, and I had the advantage of seeing their beautiful means of balancing—the supporting of the bearings in elastic rubber sleeves, which at 6000 revolutions absorbed vibration and allowed the bowl containing the milk to rotate about its centre of gravity instead of its geometric centre. The first compound steam turbine

[1] Discourse delivered at the Royal Institution on Friday, March 10, by the Hon. C. A. Parsons, F.R.S.

ran at 18,000 revolutions, and had slightly elastic bearings. The turbine teeth or blades were like cog-wheel teeth, set at an angle and sharpened at the front edge, and the guide blades were similar. Gradually the form of the blades was improved—curved blades with thickened backs were introduced. The blades were cut off to length from brass material rolled and drawn to the required section, and inserted into a groove with soft brass packing distance pieces between and caulked up tightly, and dummy labyrynth packings of various types introduced. The design was improved so as to reduce steam leakages and provide for greater expansion ratios.

The construction of a suitable dynamo to run with the turbine involved nearly so much trouble as the turbine itself; the chief features were the adoption of very low magnetic densities in the armature core and small diameters and means to resist the great centrifugal forces. The dynamo was also mounted in elastic bearings. Now that the turbine has found its most suitable field in large powers, and the speed of revolution is consequently reduced, elasticity in the bearings is less essential, and in large land plants and in marine work rigid bearings are now universal. I have said that steam behaves like an incompressible fluid in each turbine of the series, but as it is highly elastic, its volume increases with the succession of small drops of pressure, and the turbines have to be made larger and larger. This enlargement is secured by increasing the height of blade, by increasing the diameter of the succeeding drums, and by altering the angles and openings between the blades. All three methods are generally adopted to accommodate the expanded volume of one hundredfold in the condensing turbine.

Now as to the best speed of the blades. It will be easily seen that in order to obtain so much power as possible from a given quantity of steam, each individual row of blades must work under appropriate conditions. This, as has been found by experiment, requires that the velocity of the blades relatively to the guide blades shall be about one half the velocity of the steam, or, more accurately, equal to one half the velocity of issue from rest due to the drop of pressure in guides or moving blades. The curve for efficiency in relation to the velocity ratio has a fairly flat top, so that the range of velocity ratio for high efficiency is wide, and the speed of the turbine may be varied considerably about that for maximum efficiency without materially affecting the result.

In compound turbines the efficiency of the initial rows may be generally assumed as about 65 per cent., and of the latter rows at 75 to 85 per cent., and, considering the whole turbine, approximately 75 per cent. of the energy in the steam is delivered on to the shaft. The expansion curve may be expressed approximately by $pv = \log p_1/p_2$, where $p_1 - p_2$ is the drop in pressure across any turbine; pv is obviously not quite constant, but if a mean value is assumed the error is small. The expansion curve therefore lies between the adiabatic and isothermal curves for steam, but nearer the former, and the errors in these assumptions are found by experiment to be of much less importance than the errors in workmanship and imperfections of materials that are unavoidable in practical mechanics. The differential thermal expansions of the metal of which the turbine is made are the chief reason for large working clearances and loss by leakage, though every available means is taken to mitigate such loss.

In turbine design, the expression of the velocity ratio between the steam and blades may be represented by the integral of the square of the velocity of each row through the turbine, which is a coefficient called K. If K, for instance, as usual in land turbines, equals 150,000, then we know that with a boiler pressure of 200 lb. and a good vacuum the velocity ratio is 0·55, and the turbine is working close up to its speed for maximum efficiency. In large marine work, where weight and space are of importance, K varies from 80,000 to 120,000, or even to 140,000. With K = 80,000, a loss of efficiency of about 9 per cent. below the highest attainable is accepted. With K = 120,000, the deficit is only about 1½ per cent.

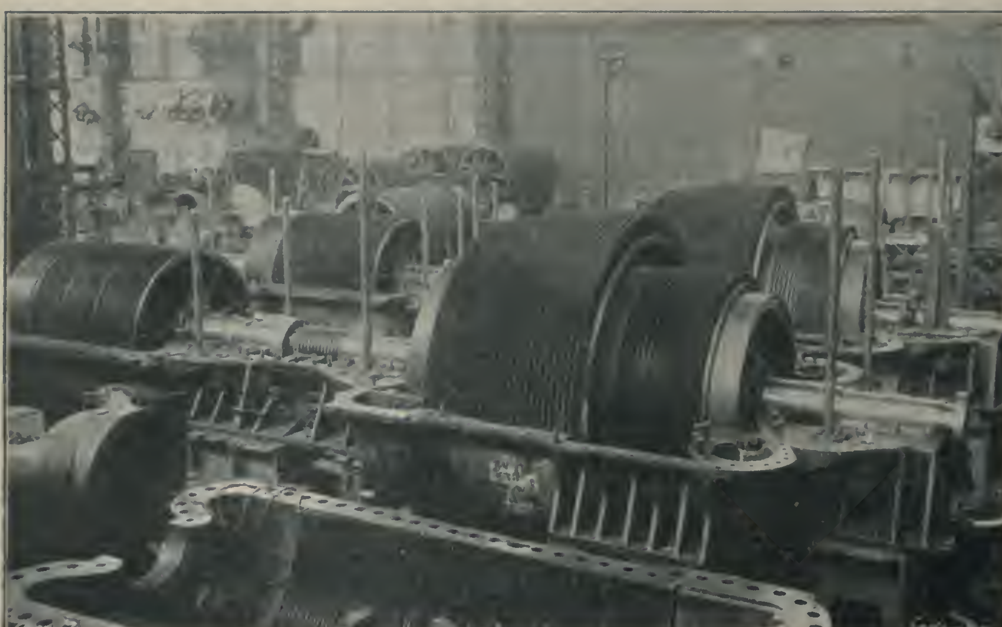

FIG. 1.—Turbines being completed. (From *Engineering*.)

There are many forms of turbines now on the market, but we need only consider four chief types, which are:—

First, the compound reaction turbine, with which we have been dealing, representing more than 90 per cent. of all marine turbines in use in the world, and about half the land turbines driving dynamos.

Secondly, the de Laval, which is only used for small powers.

Thirdly, the "multiple impulse compounded," or Curtis, which has been chiefly used on land, but which has been fitted in a few ships.

Lastly, the compound reaction type, with one or more "multiple impulse elements" added to replace the reaction blading at the high-pressure end.

We may dismiss the numerous other types as simply modifications of the original type, without any scientific interest.

Let me explain the latter types. The multiple impulse principle is the only substantial innovation since the compound reaction and the de Laval turbines came into use. It was proposed by Pilbrow in 1842, and first brought into successful operation by Curtis in 1896. A little consideration should be given to it as involving some characteristic points of difference from what has been said about reaction blading. It will be seen that Curtis used the de Laval divergent nozzle, and that he

also uses compounding, but generally only 5 to 9 stages as compared with 50 to 100 in the compound type. The same principles as regards velocity ratio apply, but owing to the repeated transfer of the steam between fixed and moving buckets at each velocity-compounded stage, the best velocity ratio in a four-row multiple impulse is only one-seventh, and the best obtainable efficiency 44 per cent., and therefore much lower than reaction blading under favourable conditions.

The good points of the multiple impulse type are that there is very little loss by leakage, and that therefore, in spite of its low efficiency, one or more multiple impulse wheels can in certain cases usefully replace reaction blading at the entry to the turbine, because in slow revolution turbines of moderate power the blades are short at the commencement, and there is consequently much loss by leakage through the clearance space. As a rule, one multiple impulse wheel is generally preferred, and is followed by reaction blading; the expansion ratio on to the wheel is about threefold, and it generates about one quarter of the whole power. Occasionally several wheels in separate chambers are placed in front of the reaction blading, but there are serious practical drawbacks to this arrangement. The multiple impulse wheel at the commencement has a further advantage in that, when highly superheated steam is used, the temperature is much reduced by expansion and work done before it passes to the main turbine casing.

The highest efficiency yet attained by land turbines has been with the pure compound reaction turbine of large size, where the high-pressure portion is contained in a separate casing of short length and great rigidity; the working clearances can then be reduced to a minimum.

The first turbine imported into Germany in 1900, of 2000 horse-power, was on this principle, and also the latest turbines, of 12,000 horse-power, which generate current for the Metropolitan Railway in London.

In marine work the same arrangement has been almost universal since 1896, when the original single turbine of the *Turbinia* was replaced by three turbines in series (on the steam) on different shafts.

Here there is the additional advantage that, owing to the power being subdivided over three shafts, smaller screws are admissible, and the speed of revolution may be increased in the ratio of 1 to $\sqrt{3}$.

Generally, the turbines are placed two in series, as in cross-Channel boats, the *Mauretania* and *Lusitania*, torpedo craft, battleships and cruisers, or sometimes three in series, as in the liner *La France* and the latest and largest Cunard liner now building. Four in series have been proposed, but not constructed.

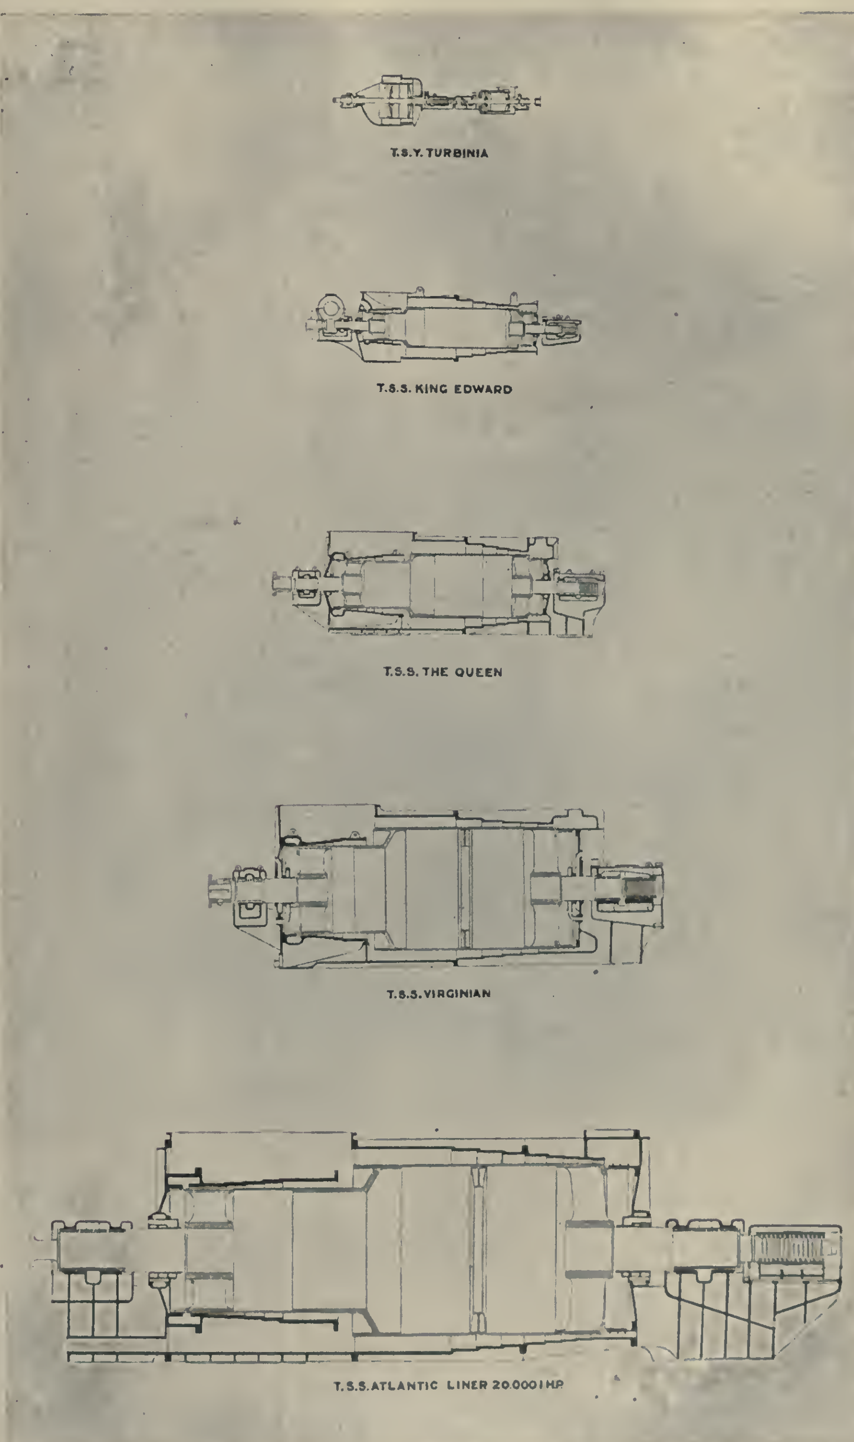

FIG. 2.—Progress in size of turbines. (From *Engineering*.)

The war vessel in commission is working at reduced

power for most of the time, and on long voyages economy of fuel is of great importance. For this purpose, additional turbines are fitted in front of the main full-power turbines. They are naturally of small size, and may be in separate casings, or the main high-pressure turbine may be lengthened by the addition of a cruising portion added on in front. All these cruising turbines or cruising elements are more or less by-passed, according as additional power is required, and at full speed they are entirely by-passed, and when in separate casings are connected to the condenser and rotate in vacuum. In some instances of modern naval construction one or more multiple impulse wheels have constituted the cruising element.

Before passing to the consideration of other applications of the turbine, I should like, with your permission, to repeat an experiment which illustrates the phenomenon of cavitation. The chief difficulty in applying the turbine to marine propulsion arose in the breaking away of the water, or the hollowing out of vacuous cavities in the water when it was attempted to force the screw above certain limits. The phenomenon was first observed by Sir John Thornycroft and Mr. Sydney Barnaby. In order to avoid cavitation, which involves great loss of power, propellers in all fast vessels are now made with very wide blades covering about two-thirds of the disc area, which gives a very wide bearing on the water, and prevents its giving way under the force.

In models, and in vessels of moderate speed, the forces are not sufficient to tear the water asunder, but if the pressure of the atmosphere is removed, a model screw will cavitate at a comparatively moderate speed.

The marine turbine, with the modifications we have so far described, is only suitable for vessels of more than 16 knots sea speed, and to make it suitable for the remaining two-thirds of the tonnage of the world has been our constant aim. The first plan to this end to be adopted is somewhat in the nature of a compromise, and is called the combination system, because the reciprocating engine is used to take the first part of the expansion and the turbine to complete it. From what we have said it will be apparent that this coalition of the reciprocating engine and turbine is a good one, because they each work under advantageous conditions. The reciprocating engine expands the steam to about atmospheric pressure, and the turbine carries on the expansion with high efficiency down to the pressure in the condenser. Now, though a large and high-speed turbine deals with the high-pressure portion of the expansion as economically as a reciprocating engine, a slow-speed turbine cannot be made to do so; but, on the other hand, a slow-speed turbine expands low-pressure steam much further and better than any reciprocating engine. In this system the turbine develops about one-third of the whole power.

About fifteen years ago I filed a patent for the system, but, with the exception of fitting the British Admiralty destroyer *Velox* in 1902, few steps were taken towards its application until the turbine had become firmly established for fast vessels, because we feared the technical public would say, "You are trying to bolster up a failure of the turbine." About three years ago Messrs. Denny, of Dumbarton, who in 1901 built the first mercantile turbine vessel, the *King Edward*, built the first combination vessel, the *Otaki*, of 9900 tons dead-weight capacity and 13 knots sea speed. She has ordinary twin screws driven by triple-expansion engines exhausting into a turbine driving a central screw. The initial pressure at the turbine is 9 lb. absolute, and it generates one-third of the whole power. The combination vessel was found to consume 12 per cent. less coal on service than her sister vessel *Orari* on the same service, fitted with quadruple reciprocating engines.

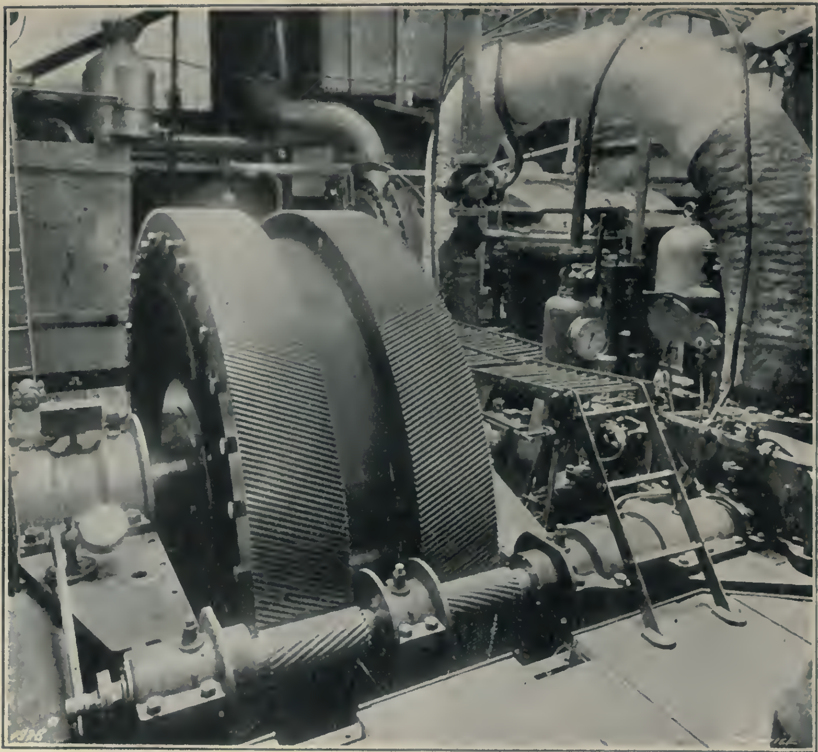

FIG. 3.—The gearing of the *Vespasian*. (From *Engineering*.)

The next combination vessel was the *Laurentic*, of 20,000 tons, built by Messrs. Harland and Wolff, a sister vessel, the *Megantic*, being fitted with quadruple engines, and on service at the same speed the saving in coal by the combination is 14 per cent.

Messrs. Harland and Wolff are also fitting the combination system in the White Star liners *Olympic* and *Titanic*, of 60,000 tons displacement, and some other companies at home and abroad are also adopting the combination system.

There is another alternative solution which promises to extend the field of the turbine further over that of the reciprocating engine. We mentioned before that de Laval had in the 'eighties introduced helical tooth gear for reducing the speed of his little turbines. For twenty-three years it has worked well on a small scale. Recent experiments, however, have led to the assurance of equal success on a large scale for the transmission of large powers of many thousand horse.

After some preliminary experiments some years ago on helical reduction gear, which showed a mechanical efficiency of more than 98 per cent., a 22-feet launch was constructed in 1897; the working speed of the turbine was 20,000 revolutions per minute, which was geared in one reduction of 14 to 1 on to the twin-screw shafting driving twin propellers at about 1400 revolutions. The speed attained was 9 miles per hour, and this little boat was many years in use as a yacht's gig.

The next step was the purchasing of a cargo boat in 1908, the *Vespasian*, of 4350 tons displacement, and triple expansion engines of 900 horse-power. After thoroughly overhauling and testing her existing machinery for coal and water consumption, the engines were replaced by

geared turbines, the propeller, shafting, and boilers remaining the same. On again testing for economy a gain of 15 per cent. was shown over the original machinery, and subsequent minor alterations have increased this gain to 22 per cent. There are two turbines, a high pressure and a low pressure, each driving a pinion at 1400 revolutions, gearing into a main wheel on the screw shaft making 70 revolutions per minute. The gearing is entirely enclosed in a casing, and is continually sprayed with oil by a pump. Ordinary centrifugal governors on the turbines control the speed, and because of the enormous angular momentum of turbines (some fifty times that of an ordinary marine engine) the acceleration is so slow that the governors have time to act, and consequently no racing has ever occurred in the heaviest weather, and it is certain that if geared turbines come into use there will be no more cases of broken screw shafting as has hitherto been common with reciprocating engines.

The vessel has now been carrying coal from the Tyne to Rotterdam for about a year, and has covered about 20,000 miles and carried 90,000 tons of coal across the North Sea. The pinion on the lecture table was specially removed from the vessel last week for this lecture, and shows a wear on the teeth of under 2/1000″ in this time, and its life will therefore be equal to or greater than that of a vessel.

Gearing promises to play an important part in war vessels for increasing the economy at cruising speeds. We explained the difficulty in obtaining good economy at the high-pressure end of marine turbines, and in replacing such portions by geared high-speed turbines we have a complete solution. The Turbinia Company are now constructing two 30-knot destroyers of 15,000 horse-power, wherein the high-pressure portion and cruising elements are geared in the ratio of 3 to 1 and 5 to 1 respectively to the main low-pressure, direct-coupled turbine. Their use will increase the radius of action of the vessels at cruising speed to a very considerable extent over that of any similar destroyer without gearing. Similar gearing is proposed for warships, with similar prospective advantages.

Gearing may also find a place in cross-Channel boats and liners for the high-pressure portion of their turbines, but the greatest material gain will be in extending the use of turbines to vessels of slow speed.

Gearing enables very high coefficients to be used in marine work at full speed, and good coefficients at all speeds without much increase in weight, and under such conditions a geared high-speed reaction turbine is much more efficient at the high-pressure end than the multiple impulse wheel or wheels we have considered, and will probably dispense with their use generally. Gearing in marine and land work promises to give to the turbine a level consumption curve like that of the gas and oil engine. Half a century ago nearly all screw vessels had mechanical gearing, one element being composed of wooden teeth, for gearing up the speed of the engine. Subsequently the speed of engines was increased, and gearing abandoned. Now a very slow-speed turbine is an impossibility, and accurately cut steel gearing seems to be a permanent and satisfactory solution.

Low-pressure turbines worked by the exhaust steam from other engines are coming into general use on land under the name of "The utilisation of exhaust steam," for they utilise what was formerly a waste product, the exhaust steam from non-condensing engines.

They are generally employed in the generation of electricity or in the working of blast-furnace blowers and centrifugal pumps and gas forcers, but recently an exhaust turbine of 750 horse-power has been applied to driving an iron plate mill in Scotland. The turbine revolves at 2000 revolutions per minute, and by a double reduction of helical gears drives the mill at 70 revolutions. A flywheel of 100 tons weight revolving at the same speed as the rolls equalises the speed. During each rolling the turbine and flywheel collectively exert 4000 horse-power, the maximum deceleration at the end of each roll being only 7 per cent.

So satisfactory has gearing proved up to the present on a small and also comparatively large scale that it seems probable that by its use turbines will be more widely adopted in the future for power purposes generally.

There are at the present time just above 6,000,000 horse-power of marine turbines completed and building, and also an equal horse-power of land turbines of the compound reaction type.

AUSTRALASIAN ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE.

THE Australasian Association for the Advancement of Science held its thirteenth meeting at the Sydney University on January 9–14 inclusive. In a short article in our issue of February 23 last (vol. lxxxv., p. 558) a brief outline of the proceedings at the meeting was given. We have now received from Mr. J. H. Maiden, the permanent honorary secretary of the association, an extended account of the meetings and presidential addresses delivered in the various sections, and are glad to publish a fuller report of what proved an important and successful gathering of Australasian men of science and their friends.

The president for the year, Prof. Orme Masson, F.R.S., professor of chemistry in the University of Melbourne, presided over the meeting, which was attended by more than 500 members, the membership being above 800. Every State in the Commonwealth was represented, and also the Dominion of New Zealand.

The president gave a garden-party in the afternoon of January 9, and delivered his address in the evening in the Great Hall of the university. His Excellency the Governor, Lord Chelmsford, was in the chair.

The work of the meeting was divided among eleven main sections, each with its own president, vice-president, and secretary. The following is a list of sections with the name of the presidents :—

Section A, Astronomy, Mathematics, and Physics: Prof. T. H. Laby, professor of physics in Victoria College, Wellington, N.Z. Section B, Chemistry, Metallurgy, and Mineralogy: Prof. B. D. Steele, professor of chemistry in the University of Queensland, Brisbane. Section C, Geology: Prof. P. Marshall, professor of geology in the University of Otago, Dunedin, N.Z. Section D, Biology: Mr. F. M. Bailey, Government botanist at Brisbane. Section E, Geography and History: Prof. G. C. Henderson, professor of history in the University of Adelaide. Section F, Anthropology and Philology: Mr. Edward Tregear. Section G—two departments, (1) Social and Statistical Science: Mr. E. W. H. Fowles; (2) Agriculture: Prof. W. Angus, late director of agriculture in Adelaide. Section H, Engineering and Architecture: Mr. Ellwood Mead. Section I, Sanitary Science and Hygiene: Dr. W. Perrin Norris, Commonwealth Director of Quarantine, Melbourne. Section J, Mental Science and Education: the Rev. E. H. Sugden.

Prof. Masson spoke first of the earliest attempts to bring about a visit of the British Association to Australia. In 1909 the matter was brought under the notice of the Australasian Association, of the universities and scientific societies of Australia, and of the Federal and States Governments. All united in cordial support of the proposal, and old financial difficulties were dispelled by the far-sighted generosity of the political rulers. The Government of the Commonwealth, acting officially for all Australia, sent a formal invitation, which was unanimously accepted by the British Association for the year 1914. Prof. Masson said it was his good fortune to attend the Sheffield meeting last September, and to speak there with the High Commissioner as the inviting deputation; and he bore testimony to the hearty feeling that prevailed and to the strong desire shown by many of Britain's most distinguished men of science to profit by this opportunity of seeing Australia, to study its science on the spot, and to play a part in what will surely prove a great event in the history of imperial unity.

He went on to describe recent advances in chemistry. He dealt first with the atomic theory, and proceeded to explain with great clearness ionic dissociation, conductivity through gases, molecular collision, the periodic law, radioactivity, and the transmutation of metals. Towards the end of his address he referred to the theory of the spontaneous transformations of the atom, whereby new kinds of atom, both electrical and material, are produced, some of the latter having but a short life before they in turn

undergo spontaneous disruption like their parents. Recent as this theory of successive atomic transformation is, it may be regarded as proved; proved by mathematical analysis and quantitative observations, proved by its explanation of a host of related phenomena, proved by its successful predictions of previously unknown facts. Perhaps the most interesting thing about it is that it confirms and tends to complete the old atomic theory. The transmutation of elements is proved at last, but man has not learned to cause it; he has only learned that it has been going on in nature since the beginning. Perhaps, in utilising the intense energy of the natural radio-active transformations of radium, or its emanation, we may succeed in influencing the life-history of other, more sluggish, atoms, and thus hasten transmutations which would otherwise be so slow as to escape our observation altogether. Ramsay has done some work in this direction, and has got some curious and interesting results, but it is too early to speak with certainty of their meaning. One extension of the disintegration theory, however, seems unavoidable. The power of spontaneous disruption, involving the creation of new atoms out of old, can hardly be the exclusive property of uranium, radium, thorium, and a few other elements of large atomic weight; it must rather be an inherent property of atoms generally.

The president closed with a few remarks of local interest. "The great advances that I have sketched," he said, "are, of course, attributable in the main to European workers. Yet we may, I think, take some satisfaction in the fact that teachers and students of the universities in this part of the world, or graduates who have gone home from here, have contributed somewhat from time to time. These Australasian contributions include work on the general theory of solution, on the mobilities of ions, on electrode potentials, on conductivity in aqueous and other solutions, on the dynamics of chemical change, on gaseous ions, and on radio-active phenomena. The older universities of Australasia are growing, and new ones are arising, as in Brisbane and Perth. Naturally and inevitably there is a tendency nowadays to ask of universities a greatly increased attention to more utilitarian developments of science. It is so in England, where, for instance, the University of Sheffield devotes a great department to the metallurgy of iron and that of Leeds cultivates its schools of textile fabrics, dyeing, and domestic economy. It is so in Australia, where there is a steady pressure put upon the universities to develop increasingly on the lines of technical schools. All this is, doubtless, as it must be; but it is beset with a certain danger. The risk is that the whole energies of these institutions, where teachers are always too few, and equipment is never too plentiful, will be directed towards the useful applications of science, and science itself will be neglected. This, if it occurs, will be a pitiful result, and will not tend to raise Australia among the intellectual countries of the world. Let us be a practical people and have due regard to utility; but let us also have some means and leisure to cultivate the vastly more interesting inutilities, for thus only can we hope to increase Australasia's contribution to the true advancement of science."

The evening lectures were two in number, one on January 10, by Prof. G. C. Henderson, professor of history in the University of Adelaide, who chose for his subject the "Mutation Theory of Evolution in History." The lecturer said that from 1870 onwards evolutionary philosophy has pervaded all departments of intellectual activity, and has stimulated patient and painstaking research in all directions. Physical evolution, or evolution in the organic world, was one thing; psychical evolution, or evolution of human life and affairs, was another and very different thing. He wished, he said, to state plainly that they could not apply the current theories of organic evolution to the history of any race of human beings. Few people would care to deny that the champions of the organic theory of evolution had rendered invaluable service, not only to science, but even to religion. They had challenged and laid low many a doctrine that was little better than a superstition; they had forced religious men to discriminate more carefully between what is metaphorically and what is literally true; and they had converted many an ignorant dogmatist into an earnest and reasonable seeker after truth. But it must not be imagined that victory had been all on one side. By no means. The evidence of poetry, history, philosophy, and reasoning religion was stronger than it ever was in support of the essential differences between organic and human life. It would appear from recent pronouncements that some of the leading thinkers in the medical and biological professions are disposed to reckon with the influence of mind over body more frankly and fully than they had done hitherto.

The evening lecture on January 12 was by Prof. P. Marshall, of Dunedin, professor of geology in the University of New Zealand, who chose for his subject, "Glaciers of the Southern Alps," which was illustrated by some of the most remarkably beautiful slides that have ever been produced of a wonderful region.

The evening of January 13 was devoted to a combined conversazione given by the association and the Royal Society of New South Wales in the Great Hall of the University, when a number of exhibits were shown in the hall itself, and, in addition, the laboratories of the engineering, biological, and physics schools were thrown open. Prof. J. T. Laby exhibited a fine model of the Brennan mono-rail. During the evening the Mueller memorial medal, "for researches in natural science," was presented by the President (Prof. Masson) to Mr. Robert Etheridge, curator of the Australian Museum, in recognition of his researches in palæontology and Australian ethnography.

The following extracts from the presidential addresses in the various sections will give some idea of the wide scope of the meeting.

In Section A, Prof. Laby discoursed on "Recent Advances in Physics." It is rather interesting to find, said Prof. Laby, that physicists trained in the Australasian universities are advancing science in all parts of the world. Most of the theories and discoveries in radio-activity we owe to Prof. Rutherford (Christchurch); new views as to the conduction of electricity through gases to Prof. Wellisch (Sydney); important contributions to the theory of light by President Maclaurin (Auckland); many and varied researches in ionisation to Dr. Kleeman (Adelaide); the organisation of metallurgical research at the National Physical Laboratory, London, to Dr. Rosenhain (Melbourne); the establishment of an institution for the training of those engaged in optical industries of London to Mr. Chalmers (Sydney); of spectroscopic research to Prof. Duffield (Adelaide); while Gray (Melbourne), Lusby (Sydney), Glasson (Adelaide), Florance (New Zealand), are all contributing researches in physics from various English laboratories. It is to be hoped, he continued, that in the future an increasing amount of such investigations will be carried out in Australasian laboratories, so that these laboratories will come to be generally regarded not merely as places where existing knowledge is expounded, but where new knowledge is obtained, where there flourished an enlightening spirit of investigation. "When our laboratories come to be generally regarded in the light I have described, it can but increase their reputation in all directions and make the community have that confidence in science which is so typical of the German people, and so intimately connected with their unprecedented industrial progress."

In Section B, Prof. Bertram Steele chose for his subject "Inorganic Solvents." He said the solubility of a pure substance depends very obviously on the nature of the solvent. We thought of barium sulphate as being a most insoluble salt, being insoluble in weak or strong acid or alkaline solutions; but it should be borne in mind that all such solutions contained water, and by the substitution of pure sulphuric acid for the water it would be found that a large quantity of barium sulphate could be got into solution. Liquefied ammonia, largely used at present on the commercial scale for the manufacture of ice, was a solvent of quite unique properties, and it has been found that two classes of substances, which from the study of their reactions alone or in water solutions were classified as "acid amides" and ammonium salts, would be regarded to-day as something equivalent to the acids had they been first investigated in liquefied ammonia. All facts pointed to the conclusion that the nature of the solvent plays a most important part in conditioning the behaviour of a given substance in solution. The result of recent work in this field showed that present theories were likely to be

modified, but not discarded, by still further investigations.

In Section C, Prof. Marshall dealt with the "Basin of the Pacific Ocean." There were, he said, various theories as to its origin. It had been suggested that it was the scar left by the moon when it came away from the earth; that the hollow had been actually inherent in the pear-shaped form the earth took on cooling; and that it was a subsidence area which had existed since the Triassic period, that part of the earth's crust having fallen in owing to shrinkage. It had been supposed that a land bridge existed between New Zealand and South America not so long ago, so as to explain the resemblances between the flora and fauna of tropical South America and New Zealand. The differences of opinion as to the age and permanence of the basin were as great as those in regard to its structure. Little certainty can be got at present. Structural, rock, and depth characteristics support the idea that the real boundary of the south-west Pacific passes through New Zealand, Kermadec, Tonga, Fiji, the New Hebrides, the Solomons, and the Admiralty Islands. This supposition practically coincides with biological knowledge as to plant and animal distributions within the area. The land connections or approximation took place, he considered, in late Mesozoic or in the Pleistocene times—probably the latter. The eastern Pacific Islands are different in structure, nature, and origin from the lands on this line, and have been peopled by chance immigrants from them. The keen controversies upon all matters of interest to New Zealand geology are, however, only to be expected. The land is so isolated, and the views of geologists have been largely based upon other countries. But at the next meeting of the congress there should be more knowledge available, for there is at present a movement on foot to make an expedition to all the eastern groups of islands in the Pacific, and to gather material for a better scientific description than there has been so far.

In Section D, Mr. F. M. Bailey gave some notes on indigenous plant life. He dealt interestingly with the longevity of seeds. A great deal depends upon the climate in which the seeds are kept. Seeds near the tropics soon lose their vitality, whereas those in a drier climate retain it for a period extending in many instances over quite a number of years. Mr. Bailey pointed out that the usual method of calculating the age of a tree by the concentric rings could not be relied upon in Queensland, for in some seasons more than one might be formed, while in others one might not be made in one or more years. Reference was made to the tenacity of life among indigenous grasses—a circumstance in which Australia is unique. During certain times of drought trees have been killed, and on digging up one of the supposed dead grasses it showed not a sign of life, but with the advent of rain the whole country, in the course of a few weeks, would be waving with grass, not alone from seed, but from these supposed dead roots. Some interesting remarks were made upon "sports" in plant life, Mr. Bailey, who had had a long experience as a cultivator of plants, expressing the opinion that most of the indigenous plants termed varieties owed their variation to "sporting" rather than to sexual reproduction.

Prof. G. C. Henderson in Section E put forward a "Plea for Colonial Historical Research." The time has now arrived, he said, when the history of the Commonwealth should be undertaken in a systematic and scientific way, and the institutions through which that might be done are the universities. The historical work done in Australian centres is preparatory, and should find its fulfilment in research. The best material for research is now available, and by means of scholarships, and especially open scholarships, the right men can be found. Prof. Henderson said that the only comprehensive history of Australia that was based upon a perusal of original and trustworthy material was vitiated from beginning to end by the author's determination to prove that the aborigines were victimised by rapacious politicians and squatters.

In Section F no presidential address was delivered, as the president, Mr. E. Tregear, was at the last moment unable to leave New Zealand.

Mr. E. W. Fowles, the president of Section G1, gave an address on unemployment. From a mass of theories and discussions, said Mr. Fowles, several principles seemed to rest on solid ground. (1) Every man should be given a chance of employment—but not necessarily continual chances. (2) Sentimental treatment of unemployment is futile; the time has come for scientific handling of the problem. (3) The problem is more than local; it is national. (4) Different conditions obtaining in different countries require different remedies. (5) There is no one cure-all. The theorists who imagine a land tax or any other one reform will automatically eliminate the unemployed have been completely discredited. (6) Although there are special conditions in different localities, the same causes produce the same results the world over. Having thus stated the set principles, the president went on to say that the points still debatable were that every workman has a claim on the State to be provided with work, and that the unemployed are a necessary and permanent factor in our present industrial system. For the purpose of scientific treatment, the unemployed might be divided into two classes, those temporarily without regular employment, and those permanently without regular employment.

The relation of science to the further development of Australian agriculture was dealt with by Mr. W. Angus in Section G2. Mr. Angus commenced by showing the progress made in wheat-growing and stock production in Australia. He pointed out that between the years 1860 and 1868 the increase in area under crop was very large—larger than for the past twenty years. The average yields were quite as good, if not better, than they had been for the last eight years. The development, so far as wheat production was concerned, has been more in the direction of extending the area under crop than in any very marked increase in the yield resulting from improved methods of agriculture. He referred to the introduction of fertilisers and the use of the drill, and the great improvement they have made in the industry. He went on to point out the great need of research work to meet the special problems of this country, and dwelt upon the want of finality under the present separate State systems. Some problems are causing a loss of thousands of pounds from year to year. In the investigation of several of them really good work has been done on individual lines, but it had been left just at a stage in which it is of little practical use to anyone. He then dealt with a number of the more urgent of these problems in regard to which combined action was highly necessary. "Take-All" is rapidly spreading in Australia, and it is most desirable to do something at this stage to check it. "Bitter Pit" in apples, a disease not yet investigated, is causing great loss to the fruit industry, and requires immediate attention.

Referring to "dry-farming," he directed attention to the way the wheat areas are being extended into the country of light rainfall, and said that if the Australian farmer could grow wheat profitably in, say, more than 2,000,000 acres of land in each of the four wheat-growing States, then this is a matter which ought to be taken up without delay, and with some of the spirit and in the business-like manner that practical men and men of science are doing in America.

America has instituted a system of soil surveys, the envy of every progressive agricultural community. That work of this kind should be of value to the Australian producer must be evident to all, and what is most needed before anything is undertaken is an agreement among the States as to a definite system, so that from the commencement they might be working on similar lines.

Among other things needing attention is the work of wheat improvement by selection and cross-breeding. Then there is the investigation of such diseases as "Dry Bible" and red rust in wheat, and the raising of varieties immune from attack. There is also the question of strength in flour, and the fixing of a uniform method of determining same, the process of nitrification under Australian conditions, the arrangement of a more uniform system of experimental work, and the comparison and publication of results, investigation into the quality and composition of surface and artesian waters as regards their suitability or otherwise for irrigation.

What is wanted is not a Royal Commission to report, but a body of trained workers to tackle the matter on

systematic lines. Such action has been taken by organisations similar to theirs—for example, the Agricultural Education Association of Great Britain and the Breeders' Association of America. The opportunity seems a good one for the Australasian Association to associate itself with questions of practical importance to the agricultural industry.

Agriculture has to run upon more scientific lines, and the farmer must be even more of a trained producer than in the past. There must be a change in the relations of the man of science and the farmer. They must become more and more co-workers, and have many more interests in common. Hence there must be some half-way meeting-place, and he could think of no more suitable institution than the experimental farm properly equipped and rightly conducted. These farms should be controlled by trained men. They should also be properly equipped—laboratories, workrooms, special implements, and special conveniences. Mr. Angus suggested the establishment of a Central Research Station on the lines of the great institution at Rothamsted. Failing that, the establishment of a Federal Research Station, properly equipped and staffed by the very best men the Commonwealth could provide, would meet the case.

In Section H, dealing with engineering and architecture, Mr. Elwood Mead, chairman of the Victorian State Rivers and Water Supply Commission, submitted a paper on the conservation of water in Australia. In two-thirds of this continent, said Mr. Mead, it is doubtful, seeing that the average annual rainfall is less than 20 inches, whether, with the most economical usage, enough water can be conserved to permit of all the land being occupied or all the mines worked, and it is certain that wasteful or improvident use will mean that large areas of fertile and fruitful soil must for ever remain barren. The Commonwealth Government should, he said, move in the matter, and if that is not feasible, then there should be concerted action by the States. Among the questions this investigation would deal with were the source, the extent, and the probable permanency of underground supplies. In Queensland alone the wells which tap this underground reservoir have a length of more than 310 miles, and had cost above 2,000,000*l*. Nearly 2000 bores had been sunk there. Prof. Gregory had estimated that in 1903 the wells of New South Wales discharged about 22,000,000 cubic feet a day, and those of Queensland 63,000,000 cubic feet. Since that time the number of wells and the discharge had increased. Much of this water is wasted, the prevailing practice being to allow the water forced to the surface to escape. Consequently there is loss by soakage and evaporation. Seriously, Australia should consider whether it is wise to allow this waste to continue.

That the supply is not unlimited, said Mr. Mead, need not be argued. Not only is it limited, but it is less than will be needed for domestic and stock purposes alone. Artesian supplies could not be expected to provide for it. Just how limited the supply was, and how long the flow would continue, were the vital questions. Should the conclusions of Prof. Gregory be correct, the exhaustion of Australia's underground reservoir was inevitable, and it would go out like a snuffed candle.

The presidential address in Section I was delivered by Dr. W. P. Norris, Commonwealth Director of Quarantine, on "Public Health Ideals." Dr. Norris quoted some striking examples of disasters brought about by man's blind dealings with nature. But this rashness, this capacity for experiment and adventure, is the very essence of progress; and, finding he has suffered, man has sought to know more of the world in which he is placed that he may save himself. As his knowledge gathers in volume and becomes precise and ordered, so the beginnings of sanitary science are reached. Man has already furthered his own evolution considerably, half-unconsciously, and for his personal advantage. Science seeks to discover the all-powerful, the all-mighty, the abiding, the permanent, the eternal, in and behind things. There can be little doubt but that to-day man is within reach of real and abiding knowledge, and that if he but has the will, the earnestness, and high seriousness necessary, he may enter into his kingdom—the Regnum Hominis of which Bacon believed, and of which Ray Lankester has more recently told in his Romanes lecture. Science urges the deliberate assumption of his kingdom by man as an absolute duty, in order that he may make good his position in the kingdom of living things, and avoid the holocausts of the past.

The presidential address in Section J, mental science and education, was delivered by the Rev. E. H. Sugden, who spoke of music as an instrument of education.

The principal resolutions passed by the council of the association were the following:—

Magnetic Observatories.—"In view of the great scientific importance of continuous magnetic observations at selected stations, the council most strongly urges the establishment of magnetic observatories at Perth and Port Darwin, to supplement the long-continued and extremely valuable magnetic work of the Melbourne Observatory. The council learns with gratification that the reduction of the forty years' observations of the Melbourne Observatory is now completed, and would earnestly request that the Victorian Government authorise the printing of the results." The foregoing resolution to be brought to the notice of the Commonwealth, Victorian, and Western Australian Governments.

Seismological Equipment.—"That the council directs the attention of the Governments of Western Australia, South Australia, New South Wales, and Victoria to the desirability of increasing and improving the seismological equipment of their respective observatories, in order to fulfil such modern requirements as are represented, for example, in the first-order seismological station in the St. Ignatius College Observatory at Riverview."

Physical and Chemical Data.—"That a committee, consisting of Prof. Masson, Prof. Warren, Prof. Laby, and Dr. Love as secretary, be appointed to cooperate with the International Commission for the collection and annual publication of all determinations of physical, chemical, crystallographic, and engineering constants, and that a sum of 25*l*. be granted towards the work of the committee."

Meridian Observatory.—"That the Australasian Association for the Advancement of Science respectfully directs the attention of the Government to the following resolution, which was passed at the International Astrographic Conference held in Paris in 1909. This resolution the association most strongly supports." Resolution referred to:—"Considering the very small number of observatories in the southern hemisphere organised for work of high fundamental precision, it is very desirable in the interests of science that a meridian instrument of the most modern type should be installed in Australia."

Teaching of Elementary Geometry.—"That, pursuant to the provisions of the resolution carried in Brisbane with regard to the teaching of elementary geometry, a committee, consisting of Prof. Carslaw, Mr. Lucas, Mr. R. H. Roe, with Mr. P. Board as secretary, with power to add to their number, be appointed to carry out the instruction contained in the last half of the Brisbane resolution."

Yass-Canberra Observatory.—"That the council of the A.S. express its gratification of the action taken by the Commonwealth Government in regard to the creation of an observatory at Yass-Canberra, and would recommend that in order to comply with the request of the International Union for Solar Research, brought before the council at the Brisbane meeting in January, 1909, such observatory be designed to fill, amongst other requirements, those of a solar observatory."

Australian History.—"That in the opinion of this association it is desirable that the governing bodies of the public libraries in Sydney, Melbourne, Adelaide, Brisbane, Perth, and Hobart, should communicate with the Secretary of State for the Colonies, asking that duplicates of the despatches that passed between the Governors of the colonies and the Secretaries of State up to a date fixed upon by the Secretary of State should be placed under their charge, and that a copy of this resolution be forwarded to the secretary of each of the libraries aforementioned."

Australian Aborigines.—"That the general council be requested to communicate with the State Premiers, directing their attention to the advisability of adopting a uniform method of spelling Australian place-names."

"That the system of orthography for native names of

places adopted by the council of the Royal Geographical Society, the Foreign and Colonial Office, the Admiralty, and the War Office be used."

"That an organised scheme for the future of the Australian aborigines be formulated and submitted for the consideration of the Federal and State Governments, and that the following be a committee to collect evidence, draw up and submit a proposed scheme to aid these authorities in the event of their consenting to take up the question, and that such scheme receive the support of the association:—Prof. J. Wilson, Dr. Norris, Prof. Baldwin Spencer, Prof. Stirling (Adelaide), Mr. Gillen, Rev. Dr. G. Brown, Archdeacon Lefroy, Dr. Cleland, with power to add to their number."

Anthropometric Tests.—"(1) This section recommends that all anthropometric measurements under the control of the Australasian Governments be based on the schedule of the British Anthropometric Committee. (2) That the advantage of utilising for this purpose the existing machinery for medical inspection of school children in the various States, and of the compulsory cadet service of the Commonwealth, be urged on the authorities concerned. (3) That a committee, consisting of Profs. Masson, Lyle, and Osborne, Drs. Norris and Harvey Sutton, Mr. Tate, Colonel Watson, and the Public Works Architect, be appointed to investigate the subject of ventilation in buildings, and that the committee be asked to present a report to the next meeting (Melbourne)."

General Recommendation.—"That the president of the association be requested to communicate with the Prime Minister of the Dominion of New Zealand, and place before him the desirability of proceeding with the work of describing and publishing the results of the examination of the collection of fossils made by the officers of the Geological Survey of New Zealand, and deposited in the Dominion Museum, Wellington."

"That it is important in the interests of higher education that additional university teaching should be provided in the department of philosophy, more especially in the subjects of sociology and experimental psychology."

"That a time limit be set for authors of papers read before the association, which shall not be exceeded except by special arrangement made beforehand with the sectional committee."

"That a general discussion on 'The Eucalypts and their Products' be brought forward at the Melbourne meeting."

Geophysical Observatory at Barren Jack.—The sum of 50*l.* was voted to assist in defraying the expense of establishing a geophysical observatory near Barren Jack reservoir, for the purpose of attempting to measure the amount of earth tilt under load.

Survey Work around New Zealand.—"That, in the opinion of the Australasian Association, the investigation of the continental shelf around New Zealand and the islands of the south of New Zealand is a work of pressing necessity, both for scientific and for economic reasons; and the association, while recognising the value of the work already done in this direction, would urge upon the New Zealand Government the desirability of taking advantage of the facilities offered by the stay of the Antarctic exploring ship, *Terra Nova*, in New Zealand to complete the survey of the surrounding seas by soundings and dredgings as far as possible."

Protection of Forests.—"That, in view of the vital importance of the conservation of water in Australia by the protection of forests and timber around the sources of its rivers and streams, and which was to have been considered at the present congress, but was deferred until the next meeting in Melbourne, by resolution carried last Monday, it is advisable that a special committee be now appointed to deal with the question in the meantime, and also bring it to the notice of the several Governments of the Commonwealth, in order to prepare the way for a more successful result when dealing with the matter at the Melbourne meeting."

Geological Committees.—(1) A committee to inquire into the question of the classification of the Permo-Carboniferous of Australia, with a view to the revision of the nomenclature. (2) A committee for recording structural features in Australia. (3) A committee to investigate and report on the glacial phenomena in Australasia. (4) A committee to investigate questions of quaternary climate in Australasia. (5) A committee for the investigation of the alkaline rocks of Australasia.

Tidal Survey.—"The Australasian Association for the Advancement of Science at its Sydney meeting in 1911 views with satisfaction the successful establishment by the New Zealand Government of the Tidal Survey, and trusts that at many of the outlying islands automatic tide gauges may be established, and the results systematically analysed. It directs that a copy of this resolution be forwarded to the Prime Minister of New Zealand."

Scientific Literature.—"That a committee be appointed to consider the steps which should be taken with a view to the compilation of a list, as complete as possible, of the scientific serial periodical literature, both in public and private possession in each of the principal centres of Australia."

The council passed the following resolutions with regard to Antarctic exploration:—"This committee recommends that the sum of 1000*l.* be paid from the funds of the association towards the expenses of the proposed Antarctic expedition, on the following conditions:—

"(1) That the expedition be under the supreme command of Dr. Mawson, free from control by any authority outside Australia.

"(2) That the details of the scientific work and the appointment of the members of the expedition be placed in the hands of a special committee of the association, such committee to have full power, subject to the approval of the leader of the expedition. But this condition shall be open to modification after consultation with the Commonwealth Government.

"(3) That Sir E. Shackleton's full consent to the first condition be first obtained.

"(4) That the sum subscribed be spent upon instruments, which shall become the property of the association on the conclusion of the expedition."

The Governor, Lord Chelmsford, gave a garden-party at Government House, Rose Bay. The association received similar hospitality from Miss Macdonald, principal of the Women's College.

The president of St. Ignatius College, Riverview, invited the members of Sections A and C to visit the college to inspect the fine seismological observatory installed at the college. Other invitations were received from various engineering departments of the State. Dr. Harvey Sutton, of Melbourne, gave a demonstration showing how to make and to throw boomerangs.

Prof. T. W. Edgeworth David was unanimously elected president for the next meeting of the association, which will be held in Melbourne in 1913.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

The thirty-eighth annual dinner of the old students of the Royal School of Mines will be held on Thursday, May 4, at the Café Monico, Piccadilly Circus, W. The chair will be taken by Sir Thomas H. Holland, K.C.S.I., F.R.S. Tickets may be obtained from the hon. secretary, Mr. Arthur C. Claudet, 6 and 7 Coleman Street, London, E.C.

On Tuesday, April 25, at 10 a.m., Mr. Clifford Dobell will commence a series of twenty lectures on the structure and life-history of the Protista (Protozoa and Protophyta) in the zoological department of the Imperial College of Science. The lectures will be given on Tuesdays and Thursdays at 10 a.m., and will be followed by practical work on Wednesday, April 26, at 5 p.m. Prof. E. W. MacBride, F.R.S., will begin a course of sixteen lectures on "Experimental Embryology." These lectures will be given on Wednesdays and Fridays at 5 p.m., in the zoological department of the Imperial College. Practical work in connection with the lectures will be given twice a week, at times to be arranged. Both Prof. MacBride's and Mr. Dobell's lectures are free to the public.

In *The School Review* for April a report appears of a lecture by the superintendent of schools at Munich, Dr.

Kerschensteiner, in which he describes the compulsory continuation schools of that city, where more than 90 per cent. of the children between the ages of six and eighteen are in attendance at one class or other of public school, and where the pupils in the compulsory continuation schools average 330 hours per annum of attendance. These schools are of two kinds, a highly organised kind for youths between the ages of fourteen and eighteen during their apprenticeship, at which they receive instruction in specific relation to their trades, and a continuation school for girls, at which three years' attendance is compulsory subsequent to the close of the primary-school career at the age of thirteen. The boys' schools cater specifically for every trade in which there are twenty-five apprentices, and there are fifty-two special trade schools as well as twelve general schools. The girls' course of instruction, at present, deals almost exclusively with domestic matters, but attention will be devoted to industrial affairs as the scheme is thoroughly developed. "The only path to real State-community," remarks Dr. Kerschensteiner, "is to accustom the children from their earliest years to do their work, not only for their own personal advantage, but also for the advantage of their youthful companions. Only thus can we hope to develop the two great fundamental virtues of devotion to aims outside ourselves and of consideration for the interests of others. And only thus will it in all probability be possible to preserve our great modern constitutional States from the dangers which threaten them through their own industrial, economic, social, and political development."

At the afternoon sessions of the forthcoming Imperial Education Conference, which will be held on April 25–28 inclusive, the following papers will be read and followed by discussion:—Tuesday, April 25: Mr. H. J. Mackinder, M.P., the teaching of geography from an imperial point of view, and the use which could and should be made of visual instruction; Prof. H. E. Egerton, some aspects of the teaching of imperial history. Wednesday, April 26: Mr. Marshall Jackman, experimental work in the teaching of arithmetic in elementary schools; Mr. J. G. Legge, practical education in elementary schools; Mr. J. Strong, secondary education in Scotland. Thursday, April 27: Dr. J. A. Ewing, C.B., F.R.S., engineering education; Mr. J. H. Reynolds, higher technical instruction. Friday, April 28: Mr. R. Blair, trade schools; Mr. Graham Balfour, continuation schools. These sessions will be held at the Foreign Office, and persons who have special knowledge of, or interest in, the various subjects which are to be dealt with at each particular session have been invited, but in view of the small space available the number of invitations has had to be strictly limited.

The London County Council has recently decided to make a maintenance grant of 8000*l.* to the Imperial College of Science and Technology, South Kensington, S.W. In return for this grant it secures the privilege of nominating twenty-five students for one year's free instruction at the Imperial College. These places are to be filled as from October, 1911. The instruction will be of an advanced nature, and therefore only advanced students who are qualified to enter on the fourth year of the course should apply. There is no restriction as to income, but intending candidates must be ordinarily resident in the administrative county of London, and must be students at an institution aided, maintained, or approved by the Council, for this purpose, who have attended regularly courses of instruction for at least two sessions. The free studentships do not entitle the holders to any maintenance grants, but cover all ordinary tuition fees. No examination will be adopted for the final selection of the students from the applications received. The free studentships will be awarded on consideration of the past records of the candidates, the recommendations of their teachers, the course of study they intend to follow, and generally upon their fitness for advanced study in science applied to industry. It is quite possible that, in special cases, the free places may be extended to two or more years. Application forms (T. 2/268) can be obtained from the Education Officer, London County Council, Victoria Embankment, London, W.C., and must be returned not later than Saturday, May 27, 1911.

The summer field session for 1911 of the School of American Archæology, of the Archæological Institute of America, will be held at El Rito de los Frijoles, near Santa Fé, New Mexico. Facilities will be given students to observe or to participate in the excavations, begun in 1908, and now in progress at Tyuonyi, near by talus pueblos and cliff-dwellings. Excursions will be made to facilitate a study of botanical and other environmental conditions of the tribes dwelling in the vicinity. During August, lectures will be given on the distribution and culture of the tribes in the south-western section of the United States; on the evolution of design as shown in ancient Pueblo art; on the native languages, and methods of recording them. A course will be given by Dr. Lewis B. Paton, formerly director of the American School in Jerusalem of the Archæological Institute of America, on "The Ancient Semites," to afford an opportunity of a comparative study of cultures developed in semi-arid regions in the eastern and in the western continents. The object of the annual summer field session of the School of American Archæology is to bring together persons interested in the study of anthropology, for investigation and discussion, and to give students the opportunity for field work needed to supplement university instruction. At the close of the session opportunity will be given to visit the pueblos of Taos and Acoma, and the Government excavations among the cliff-dwellings in the Mesa Verde National Park, Colorado. Details of the summer session may be obtained from the Director of the School of American Archæology, Santa Fé, New Mexico.

The council of the Teachers' Guild has addressed a letter to the Board of Education on the subject of cooperation between labour exchanges and local education authorities, approving the principle of such cooperation, provided that the employment of juveniles be primarily considered from the point of view of their educational interests and permanent careers. The guild recommends that the subcommittees to be appointed for this work should include county councillors, H.M. inspector and council inspectors, directors of technical and continuation classes, representative employers and workmen, and representatives of the head teachers, of the school managers, and of the care committees (where they exist). The central offices for this work should be located within, and form part of, the offices of the local education authority, and from age fourteen to seventeen the "juveniles" should be, to some extent, under the supervision of the education officers of the county authority. The letter points out the important results which may flow from the adoption by local authorities of the powers offered to them by the Education (Choice of Employment) Act, 1910. We quote the following passages, which summarise views frequently expressed in Nature:—"In the past the lack of adequate linkage between the work of the ordinary schools and that of technical classes has been felt to be a most serious hindrance to technical education. The removal of this hindrance is desirable, but of greater future importance is the opportunity for systematic schemes for the continued education of boys and girls *directly after they have left school*. . . . The experience of teachers, and of those engaged in research into mental development, points to the enormous importance of the period between fourteen and seventeen years. . . . The work of ordinary elementary and secondary schools should be in closer touch with everyday life. . . . Some of the work of continued education should be done in day schools. The cooperation of employers is essential."

Forty-one annual conferences of the National Union of Teachers have been presided over by men whose addresses have received and deserved considerable public attention. This year, for the first time, a woman took the presidential chair, and special interest therefore attaches to her speech. We recognise in Miss Cleghorn's address a womanly regard and sympathy for the children, which in no wise detracts from the breadth of view evinced by her chairmanly utterance. Dealing first with the infants' departments, she deprecated the exclusion of young children under five when home conditions do not permit adequate maternal care and training. Again, it is a disastrous policy to promote children to the older depart-

ments before they are fit, as is frequently done for the sake of higher grants. For the lower standards in the boys' and girls' departments she claimed more freedom, more activity, a better bridge from the infants' school. She asked that in the ordinary schools there should be a later leaving age, a more suitable curriculum, smaller classes, better attendance. All education up to twelve should be primary in name and practice. The transition to secondary schools should be easy for all scholars about the age of twelve years, and secondary schools of varying types should provide the coping-stone of primary education. Miss Cleghorn pleaded for the abolition of half-time, for a more vocational bias in the work of the present secondary schools, and for the extension to England of the powers already granted to Scotland of enforcing attendance at continuation schools until the age of seventeen years.

AMONG other matters of wide interest which were brought before the National Union of Teachers at the Aberystwyth conference we note especially the careful statement of the difficulties attending ameliorative medical work, contributed by Dr. Lewis Williams, the Bradford medical superintendent. At the Bradford school clinic 6446 cases were dealt with during last year, of which 3520 have actually received treatment, and of these 3000 have been cured of disease, had vision corrected, or teeth attended to. It is impossible to read this paper without arriving at the conclusion that the school clinic is a valuable—even a necessary—institution, and that the case for the extension of school clinics has an appalling strength. In view of recent controversies, it was inevitable that keen interest should be shown in the subject of a paper by Mr. T. P. Sykes, "Function and Position of H.M. Inspectors of Schools in the Elementary-school System," read at the same conference. The paper was evidently written before the recent Parliamentary discussion, and its main purpose was to put forward a view of the duties of the inspectorate which is very different from the one which appears to prevail. Mr. Sykes would wish inspectors to devote their energies to securing proper conditions of work, involving adequate expenditure and administration. They should see that the Medical Inspection and the Child Feeding Acts are properly carried out, that schools are not overcrowded, that there are proper staffs of certified teachers, that salaries are such as to secure efficiency. As a professional teacher, Mr. Sykes protested against the present system of interference by inspectors with methods of teaching, and he gave instances of its deleterious effect. Mr. Sykes did not, however, suggest any method of testing the efficiency of the work.

SOCIETIES AND ACADEMIES.

LONDON.

Geological Society, April 5.—Dr. C. W. Andrews, F.R.S., vice-president, in the chair.—E. S. **Cobbold**: Trilobites from the Paradoxides beds of Comley (Shropshire), with notes on some of the associated brachiopoda by Dr. C. A. Matley. The author describes and illustrates the type-specimens of *Paradoxides groomii*, Lapworth, 1891, and the associated trilobites from the basement beds of the Middle Cambrian of Comley Quarry. Among the latter there are two or three other species of Paradoxides, represented by fragments insufficient for specific determination; also a species of Dorypyge, allied to *D. oriens*, Grönwall, and one of Conocoryphe allied to *C. emarginata*, Linnarsson. He also describes some of the trilobites from a higher horizon containing *Paradoxides davidis*, Salter, and *P. rugulosus*, Corda; and notes on the brachiopoda from this horizon are contributed by Dr. Matley. A complete list of the trilobites hitherto identified from the local Cambrian deposits is given.—Dr. D. **Woolacott**: The stratigraphy and tectonics of the Permian of Durham (northern area). The Permian strata of Durham and Northumberland lie unconformably on a basin of the Coal Measures; they may be divided into:—(4) upper red beds with salt and thin fossiliferous Magnesian Limestones (only exposed in the south of Durham), 300 feet; (3) the Magnesian Limestone; (2) the Marl Slate, 3 feet; (1) the Yellow Sands, from 0 to 150 feet. These beds, which vary much in thickness, lie in North Durham in the general form of a syncline beneath Sunderland. The unfossiliferous Yellow Sands are probably a deltaic formation reassorted by wind, the other beds being the result of deposition in an inland sea undergoing desiccation. The magnesium carbonate existed in the waters of the sea, and was either deposited along with the calcium carbonate or introduced by seepage when the beds were being laid down. Great changes in the amount and distribution of these carbonates have, however, taken place since deposition. The percentage of calcium carbonate is sometimes more than 99, while that of magnesium carbonate is occasionally as much as 50. The fauna of the Magnesian Limestone is very restricted (about 140 species) and most peculiarly distributed. The marked palæontological features are the profusion of individuals in the Middle Fossiliferous Limestone (which appears to have formed a shell-bank in the Middle Magnesian-Limestone sea), and their sudden disappearance in the Upper Limestone. No corals, echinoderms, polyzoa, brachiopods, or cephalopods have ever been found above the top of the Middle Fossiliferous division, only a few fishes, gastropods, lamellibranchs, entomostraca, and foraminifera occurring in the Upper beds. The Lower and Middle Fossiliferous Limestones are marked by the presence of *Productus horridus*, Sow. Fish-remains occur at two horizons, namely, the Marl Slate and the Flexible Limestone, and the beds above these deposits. The Brecciated beds, which occur at various horizons, chiefly, however, in the two Middle divisions, constitute the most marked tectonic feature of the Magnesian Limestone of the area. They have been produced by thrusting, which brought about a decrease in the lateral extension of the Permian. Associated with the breccias are other proofs of thrusting:—(1) thrust or shear-planes; (2) disturbed and displaced masses of Lower Limestone; (3) intruded breccias; (4) slickensided and grooved, horizontal and vertical surfaces; (5) cleavage; (6) folding, both on a local and on a general scale; (7) buckling, thickening, and squeezing-out of beds; (8) phacoidal and other structures; and (9) fissuring.

DUBLIN.

Royal Dublin Society, March 28.—Mr. R. Lloyd Praeger in the chair.—Prof. T. **Johnson**: (1) *Archaeopteris simplex*, sp.nov.: (2) Is Archæopteris, Dawson, a pteridosperm? The author gave an account of his examination of specimens of Archæopteris, Daws., in the botanical division of the National Museum, and in the Royal College of Science, Dublin. He recorded in the first part of his paper the occurrence in the south of Ireland, in the Upper Devonian beds, of *A. hibernica*, var. *minor*, Crépin, *A. roemeriana*, Göpp., and *A. Tchermaki*, Stur, in a fertile state. In the second part of the paper certain features in the structure of *A. hibernica*, Forbes, sp., are described. The more interesting features are the presence of fertile adaxial and sterile abaxial lobes in the fertile pinnule or *sporophyllule*, the vascularity of the stalk of the sporangium, and the transverse septation of the latter. The paper concludes with a discussion of the relationship of Archæopteris to the Ophioglossaceæ, the Sphenophyllaceæ, and the Pteridospermeæ.—Dr. J. H. **Pollok**: The vacuum-tube spectra of the vapours of some metals and metallic chlorides. The author showed reproductions of the spectra of the metals or chlorides of thallium, lead, copper, bismuth, iron, aluminium, chromium, manganese, nickel, cobalt, barium, strontium, calcium, magnesium, potassium, sodium, and lithium taken by means of his new quartz vacuum tube. As observed in the spectra referred to in part i. of this paper, there is invariably a marked difference between the spectra taken without a condenser and with a condenser in the secondary circuit. In the former case bands show a greater tendency to develop, in the latter there are invariably many more lines, but some become weaker. The new lines, and lines that become stronger, are very generally those showing the discontinuous lines when metallic electrodes are sparked in air, and a spherical condenser is used in photographing.

Royal Irish Academy, April 10.—Rev. J. P. Mahaffy, president, in the chair.—Major **Berry**: The Sierra Leone cannibals, with notes on their history, religion, and customs. Traces of a formerly richer flora and the remains of human settlements would tend to prove that the Sahara was subject to cyclical periods of aridity and humidity, and that in Palæographical times it possessed a climate favourable to life. It was in the Sahara that the Mediterranean race probably originated and sent forth waves of migration, one of which, moving southwards, pushed the blacks back to the unhealthy coast-line. These blacks were by the Arab historians called the Dem-Dem, and are now known as the Mampas. Formerly they must have been powerful, but are now broken up along the coast from the Gambia to the Niger. From time immemorial these people have practised cannibalism, less for food than as a sacrament, with definite ritual curiously resembling that of ancient Mexico and Egypt. There are traces of a Mother Goddess, and the symbology connected with their religion and customs suggests other than local origins. Details of the customs and cannibalistic ritual collected in the country by the author are given and discussed.

Göttingen.

Royal Society of Sciences.—The *Nachrichten* (physico-mathematical section), part i. for 1911, contains the following memoirs communicated to the society:—

November 16, 1910.—E. **Kohlschütter**: The structure of the earth's crust in German East Africa.

January 14, 1911.—W. **Voigt**: Contributions to Lord Rayleigh's theory of grating-inflexion.

December 10, 1910.—N. **Galli** and K. **Försterling**: Theoretical and experimental researches on the optical behaviour of minimal metallic films.

November 26, 1910, and January 28, 1911.—W. **Voigt**, with a note by H. A. **Lorentz**: General considerations on emission and absorption in connection with the question of measurements of intensity in the Zeeman effect.

DIARY OF SOCIETIES.

THURSDAY, April 20.

Society of Dyers and Colourists, at 8.—The Dyeing of Paper Pulp: R. Bickerstaffe.

MONDAY, April 24.

CONTENTS.

THURSDAY, APRIL 27, 1911.

A NEW CATALOGUE OF BRITISH BIRDS.

A List of British Birds, showing at a Glance the Exact Status of Each Species. Revised to August, 1910. By W. R. Ogilvie-Grant. Pp. 60. (London: Witherby and Co., 1909.) Price 1*s*. 6*d*.

THE old *order* changeth giving place to new, is true with a vengeance concerning lists of British birds, but there really does not seem to be any good reason for the changes. As all linear arrangements of birds must be unsatisfactory, why should we be annoyed with new anomalies of this kind, and constant changes in the arrangement and order of sequence of our birds in what ought to be works of reference? As if it really made any difference which comes first and comes last in the book! What the reader and student really does want to know is, whether he is to open the new book at the beginning or at the end to find, say, a crow or a duck, as the case may be. Unfortunately this is just what he cannot now know. We had become used to the change from the old arrangement which placed the birds of prey at the head, and had accepted that which began with the highly organised song-birds, but were not allowed to rest there. In the latest list now before us we begin with the game-birds (with which Seebohm ended), and end with the crows (which Sharpe put first)! And so on, and so on through all the miserable, useless changes.

The new list is printed in such a form that it can be cut up and used for labelling collections. The system adopted to indicate the status of each species is to assign each, by the use of numbered columns, to one of these five groups:—(1) Resident, breeds; (2) regular summer visitor, breeds; (3) regular autumn, winter, or spring visitor, does not breed; (4) occasional visitor, used to breed; (5) occasional visitor, never known to breed. When species have not occurred more than six times references are given to the works in which they have been recorded. But these are not, except in a few cases, to the original records. Occasional explanatory or amplifying notes are given, rendered desirable perhaps from the difficulties of grouping the birds which soon arise. For instance, the black-necked grebe seems out of place in the third column, for it is known to have bred here for years, and its breeding is mentioned in a note. The difficulties of grouping birds in this way are evidently great, and a system can hardly be considered satisfactory which leaves the avocet and great bustard (both now occasional visitors, which used to breed) in different columns, because apparently the great bustard is the rarer of the two as a visitor nowadays, and was *formerly* a resident, while the avocet was a summer visitor. Here again a note is necessary to qualify the latter's exclusion from the column "used to breed." Saunders's simple and masterly plan of indicating the status of a species by the type or fount, in his well-known list, if it did not indicate so much as the new catalogue (which the numerous additions to the British avifauna since 1907 have rendered necessary), at least had the merit of indicating that little very clearly.

The nomenclature in the present list differs somewhat from that used in the British Museum catalogues and guides, especially in the matter of such genera as Totanus and Tringa, which the author thinks (and we agree with him) have been split up for no very apparent reason. The author is clearly not a "splitter," as is evidenced by his leaving the black-headed bunting in the genus Emberiza. Mr. Grant does not use trinomials, and his acceptance of forms and races seems a little arbitrary. We may be thankful that he does not accept the British goldcrest, hedge-sparrow, tree creeper, &c., &c., although he does accept the British robin, another supposed local race, the existence of which as a subspecies is certainly not universally recognised. The square brackets, indicating species of which the history is doubtful, or which have, perhaps, been artificially introduced, seem to be somewhat arbitrarily applied; but this, it must be admitted, is largely a matter of individual opinion.

But to criticise the inclusion and exclusion of species, and the forms allowed and disallowed, would occupy too much space. Very largely, too, these are matters of opinion, and the opinions held are very diverse—the doctors differ. Yet some allusion must be made to the present attempt to indicate the modern status of our birds, insomuch as the difficulties encountered in the attempt, and already alluded to, become more apparent as we read through the list—difficulties which do not seem to be always satisfactorily surmounted. To take the honey buzzard, for instance. It is here stated to be a regular autumn, winter, or spring visitor, which does not breed, and there is a note appended that it formerly bred in Great Britain. The statement that it does not breed is a bold one, for nobody would be surprised at the discovery of a honey buzzard's nest in England any year. Its former status was undoubtedly that of a breeding summer visitor. It has become very rare, as such, of late years, and there is no recent record of its nesting. But there is no reason why birds should not arrive any year, and, if they escaped being shot by gamekeepers, breed. As in the case of other summer migrants, individuals from more northern countries pass here in autumn.

This bird and the golden oriole and hoopoe show the difficulties of this kind of concise classification. The original status of all three was "Summer visitor; breeding." But on account of their rarity, in different degrees, and the use of the word "regular" in column No. 2, a difficulty has been made of putting them all therein. Yet the hoopoe is put there with a qualifying note in almost the same words and to the same effect as that appended to the golden oriole (placed in column 4), and the honey buzzard is relegated to column 3, although the last-named bred more regularly in this country than either of the others, and while none of them breed regularly now it is not very improbable that any one of them might do so any year. The marsh harrier is included in column 3 among those birds which do "not breed," with a note appended saying that it "occasionally breeds." This really

K

amounts to saying that it retains its original status in the country, viz., resident. And this we should say is its real status—if status it has—although its numerical strength has gone down almost to vanishing point, and, as in the case of many other birds, wanderers from other parts occasionally occur. The fact is that it is almost impossible to indicate adequately the varied and often complex status of some of our birds by the present method without using such a number of columns as would make the method very cumbersome.

The "bridled guillemot" is included by name but not numbered as a species. Whatever this bird really is, its status is similar to that of the common guillemot. The greenshank, entered here as a summer visitor simply, is a winter visitor to Ireland at all events, and a spring and autumn migrant to England. Some reference is wanting to the migration of the ringed plover and to the small dark migratory race, regarded by some as a good subspecies. The claim of the stone curlew to be a resident is remarkably small and applies to one locality only. A qualifying note in the case of the little bittern might well have expressed the strong suspicion entertained of its former and recent breeding, and of its claim to be a rare summer visitor. The willow tit is not a subspecies of *P. borealis* but of *P. atricapillus*, of which *P. borealis* is itself a form. The occurrence of the latter is doubtful in the extreme. The tawny pipit is put in column 4 indicating that it "used to breed," with a note that it had bred in Sussex. But there is only one record of its ever doing so, and the reference given is to a local publication not generally available. Yet the wood sandpiper is relegated to the society of those that do not breed, and there is no mention of its undoubted former breeding in Northumberland. The shorelark is probably as regular a visitor as the Lapland bunting, yet they occupy places in 5 and 3 respectively. If the little owl (a weak candidate for the position of casual visitor until its introduction in large numbers) is to be called a "resident," there seems no reason for withholding the position from other introduced species which breed freely with us, and, given adequate protection, might maintain a wild existence in this country. The introduction is duly noted.

With regard to common names, great confusion might well arise from the quite unnecessary bestowal of the name "eared," as an alternate name, upon the Sclavonian grebe, for until recent years what is now generally called the black-necked grebe bore that name almost always. The pass to which the continual alteration of the Latin names of birds has brought us (by the raking up of ancient, doubtful, and little-known names under the plea of the law of priority) is well set before us in the present list by the fact that in order to show us exactly what bird is intended as the black-eared wheatear no fewer than five specific names (with their authorities) have been used for it and set down as synonyms; the one selected as the bird's right name (at the present moment!) being one which was long borne by another species! Thus is confusion worse confounded.

A new list of British birds was wanted, and the present one is clearly printed and well got-up. As it is printed on one side of the paper only, there is plenty of room for additions and any alterations the owner of a copy may like to make.

THE CONSERVATION OF SOIL WEALTH.

Soil Fertility and Permanent Agriculture. By Prof. C. G. Hopkins. Pp. xxiii+653. (London and Boston: Ginn and Co., n.d.) Price 10s. 6d.

PROF. CYRIL HOPKINS, of the Illinois Agricultural Station, is well known in the United States as the initiator of a systematic policy for restoring the fertility of the land of the east and middle west, which is in many respects a supplement to the great work of conserving the national resources that the late President succeeded in bringing home to the American public.

The problem is one quite distinct from the agricultural questions prevailing in western Europe. Up to the present time almost, it might be said that American agriculture has been extensive in its charter and wasteful in its methods. It has depended entirely upon the natural resources of the soil, and in many districts has only succeeded in exhausting them. In Virginia, in New England, and in many of the older States one may see great areas of indifferent farming and even of derelict land; land which has been cropped without due regard to the future until it has ceased to be profitable with the style of farming there in vogue and is now occupied only by comparatively backward cultivators, who draw but the poorest living from the soil. Even of the rich prairie lands of the middle west, in Illinois, Iowa, and Ohio, notwithstanding the enormous stock of plant food present in the soil when it was first taken into cultivation, a similar story is told. The yields on much of the land are declining, and the tendency on the part of the enterprising men to move west to the virgin soil has been very prominent of late in the migration of American farmers into those parts of western Canada that have lately been opened out.

With certain conspicuous exceptions the American farmer has always been raising a succession of crops which drew upon the resources of the soil; wheat has been alternated with corn and Timothy hay, and each crop has been either sold away from the farm or consumed in the great barns in which the stock are housed through the severe winters. In many cases the shortage of labour has prevented men from even restoring to the land the manure made by the stock, while no root crops are grown and no sheep are kept to run over the land and restore to the soil the fertilising ingredients that have been drawn from it by the fodder crops. And though the fertiliser trade in the United States is of enormous dimensions, it is too much confined to a relatively small class of intensive farmers, and does not represent a very large outlay on the total area of land under cultivation. Thus in many respects the condition of farming has been similar to that prevailing in Europe before the introduction of artificial fertilisers, that is to say,

that the farmer has been dependent upon the resources of the soil alone. In Europe, however, the cultivator has been forced by the lack of further land to a system of conservative farming which would maintain the fertility of the soil and the production of crops, at a somewhat low level, perhaps, but one that would show no decline for a very long period of time.

In the Norfolk four-course rotation, for example, all that is sold away from the farm is meat and corn; the straw, the hay, and the roots are more or less completely returned to the soil. The growth of the clover crop once in the rotation was more than capable of replacing the nitrogen sold away and the inevitable wastage. The stock of potash in the soil is so enormous as to be practically inexhaustible, and cultivation will slowly make it available. Only the phosphoric acid suffers a steady and irreplaceable loss under such a conservative system of farming, but this loss is not a very large one. Prof. Hopkins has made it his mission to awaken the Illinois farmer and his neighbours east of the Mississippi to a sense of the inevitable decline of the fertility of their land unless they also work out a similar conservative rotation, and he has shown them how this can most profitably be effected with the fertilising resources now available.

In his system Prof. Hopkins lays less stress upon the nitrogen question than we are accustomed to do in Europe. Even to-day the old prairie lands are still rich in nitrogen, and he considers that the introduction of a vigorous clover or cow-pea crop into the rotation will be sufficient to maintain the nitrogen at a profitable level for production. To secure a good clover crop it is necessary that there should be an ample supply of phosphoric acid and potash. Of the latter element the initial stock is large enough to last for many generations; all that is necessary is to bring it steadily into solution. To this end, and also to ensure the proper bacterial actions which both collect nitrogen and bring the organic nitrogen compounds in the soil into forms assimilable by plants, a neutral reaction is required in the soil, and Prof. Hopkins uses finely ground limestone in preference to the quick-lime which we more commonly employ. Then he turns to the phosphoric acid to complete the chain, and supplies this fundamental element by one of the mineral phosphates so abundant in Carolina or Florida in a finely ground condition, preferring the neutral finely ground rock to the artificially prepared acid superphosphates more common in Europe.

To Prof. Hopkins the ground phosphate is the keystone of the arch. The carbonate of lime is necessary to prepare the ground and to liberate the potash, but the phosphoric acid provides the item that was necessary for fertility, not only to the grain crops themselves, but to the nodule bacteria on the clover, which have to maintain the stock of nitrogen. Prof. Hopkins has demonstrated the success of his system experimentally at Urbana, and on many a farm in Illinois, and has taken up the propaganda of this method of restoring the waning fertility of the older lands of the United States with the zeal and conviction of a missionary. In this cause he has been brought into sharp conflict with the opinions that have issued from the Division of Soils at Washington, where Whitney and Cameron have put out their theory, which in its crude form as summarised for popular consumption, would seem to say that all soils are inexhaustible and equally rich as regards their mineral constituents, and that nothing is more required for fertility than a proper rotation and due attention to the conservation of the water supply, expenditure upon fertilisers being in the main unnecessary.

On the value of this theory and its application to practice this is not the place to enter, but the book before us is to a large extent a detailed statement of Prof. Hopkins's position and the justification of his belief in fertilisers, more particularly in ground limestone and rock phosphate, as a means of raising the level of productiveness in the United States.

Prof. Hopkins's book is designed on rather different lines from the usual treatise on agricultural chemistry, or even upon soils. After a general introduction on the elements of plant nutrition, he discusses in some detail the types of soils to be met with in the United States, and then goes on to develop his system of agriculture with an account of the materials necessary to maintain fertility. Here the reader will find a number of experimental data concerning the value of ground limestone in comparison with lime, and particularly of ground rock phosphate as against superphosphates and other manufactured fertilisers.

After a chapter of polemics on the theory of soil fertility, Prof. Hopkins proceeds to discuss field experiments, taking the Rothamsted experiments as a type of what may be expected under European conditions, and then summarising in a very convenient and interesting form for the European reader the work that has been done in Pennsylvania, Ohio, Illinois, Minnesota, and other American States. Though the book is written for the educated farmer, on this side of the Atlantic it is rather to the teacher and student that it will appeal, because our farmers will be strange to the conditions which render its main argument of so much importance. To the teacher, however, it is a mine of information; as it is also written with such vigour and refreshing conviction of the fundamental importance of its doctrine, we can well understand how Prof. Hopkins has become one of the really inspiriting forces in American agriculture.

A. D. H.

THE TERMITES OF CEYLON.

Termitenleben auf Ceylon, neue Studien zur Soziologie der Tiere zugleich ein Kapitel Kolonialer Forstentomologie. By Prof K. Escherich. Pp. xxxii + 263.2 pls. and 68 figures in the text. Jena: Gustav Fischer, 1911.) Price 6.50 marks.

THE termites (or white ants, as they are frequently though improperly called), although they belong to the order Neuroptera, exceedingly resemble the true ants in their habits, and are of almost equal interest. They are, however, tropical insects, and extremely destructive, and although one species has

established itself as far north as Bordeaux, it is fortunate that no species has yet been able to do so in the British Isles.

Prof. Escherich first devoted his attention to the termites during a tour in northern Abyssinia (Erythrea) four years ago, and, wishing to continue his studies on the same subject, selected Ceylon as most suitable for his purpose. Incidentally he estimates the number of species of termites already described as about 500, whereas about 5,000 species of ants are known. It is probable, however, that the difference is not solely due to termites having been less studied than ants, but to the number of species of the former being really much less numerous. The number of termites now known from Ceylon is thirty-five, of which four are possibly forms of others, leaving thirty-one undoubted species, nearly all collected by Prof. Escherich himself. The species of ants collected by Prof. Escherich in Ceylon number about seventy. He must have worked hard during his short stay in the island (from January 22 to the end of the first week in April), of which he gives an interesting account.

The first chapter of the main work is devoted to the nests of the mound-making termites, which vary much in form and size, and usually contain large fungus-beds. The larger termite-hills in Ceylon rise to a height of from 2 to 2½ metres, and the subterranean part is said by the natives to extend to a depth of ½ to 1 metre. The inhabitants of the nests are also described, and compared with the African *Termes bellicosus*. The latter species, however, is far more formidable, for the mandibles of the soldiers draw blood at every snap, while those of the Ceylon species can hardly pierce the skin of the hands, though they cling on firmly, and discharge an irritating liquid. Prof. Escherich disputes the usual notion that light is intolerable to termites; but it seems to us probable that this sensitiveness varies in different species. The huge size to which the abdomen of the queen termite attains is well known, but still more remarkable in the opposite direction is the figure of a soldier on p. 54, the head of which is nearly as large as the body, and the head and mandibles together much longer.

Several species of termites often inhabit one nest, and different species of ants are often associated with them in the same nests, as well as many other insects, &c. One peculiarity of the termite hills is the so-called "chimneys," open above, and running down into the nest, and efficiently providing for ventilation.

The second chapter of the book deals with the genus Eutermes, the species of which make their nests in wood, and are exceedingly destructive, while others construct long galleries, through which they march from one place to another. A third chapter is devoted to miscellaneous observations on queens, soldiers, behaviour towards light, &c., and a fourth to the economic importance of termites. Prof. Escherich considers that they are much less destructive in Ceylon than in Africa, and he discusses the best means of preventing their ravages, or of destroying them.

The book concludes with a series of valuable appendices by various authors, including descriptions of a considerable number of new species collected by Prof. Escherich, comprising termites, ants, and various Coleoptera, Orthoptera, Thysanura, Myriapoda, and Nemotoda, inhabiting the nests of termites in Ceylon.

ORIENTATION IN ORGANIC CHEMISTRY.

Über die Bestimmung des chemischen Ortes bei den aromatischen Substanzen. By W. Koerner. Pp. 132. (Leipzig: W. Engelmann, 1910.) Price 2.40 marks.

WILHELM KOERNER had the good fortune to become a student of Kekulé, in 1865, at a time when the latter was developing his benzene theory. After a year spent in Otling's laboratory, Koerner returned to Ghent as private assistant to Kekulé, and remained for a year in that capacity. He rapidly imbibed the views of his teacher, and, realising something of their far-reaching consequences, set before himself the task of experimentally demonstrating the truth of Kekulé's theory, a task which he never afterwards relinquished. The object of his first paper, published in 1866 in the *Comptes rendus*, was to link together the three series of di-derivatives of benzene. Thus, by preparing the three iodophenols and converting them by fusion with potash into the corresponding hydroxybenzenes, he was able to connect quinol with iodoaniline, iodophenol with catechol, and nitraniline with resorcinol, incorrectly regarded as the ortho, meta, and para series respectively. At the same time he criticised the speculative methods adopted by Baeyer, Graebe, and others as a basis for orientation.

In his second paper, published in 1867, he foreshadows his future method by pointing out that the trihydroxybenzene derived from the three dihydroxy-compounds must have the hydroxyls in the 1, 2, 4 position. His third paper contains a clear exposition of Kekulé's views on the constitution of the aromatic series with which we are so familiar. It is dated 1869 from the laboratory of Cannizzaro at Palermo, whither he had gone in 1867 to re-establish his health. When, later, he became lecturer on organic chemistry at the new technical college in Milan, he continued actively engaged in experimental work connected with his method of orientation, which he embodied in his fourth paper, published in 1874 in the "Gazzetta chimica italiana." It is in this last paper that Koerner collected the enormous mass of material which had been steadily accumulating since 1867.

The work, establishing for the first time by direct experimental evidence the true orientation of the simpler benzene derivatives, has taken its place as one of the classics of chemical literature, and chemists will welcome this last addition to *Ostwald's Klassiker*. The papers have been translated from French and Italian by Messrs. Bruni and Vanzetti, who have added a few explanatory notes. They have overlooked a curious transposition of the ninth line from the bottom of p. 4, which should be read as the bottom line.

J. B. C.

A PHILOSOPHICAL EVOLUTIONIST.

Der Wert der Menschheit in seiner historisch-philosophischen und seiner heutigen naturwissenschaftlichen Bedeutung. By Dr. F. Strecker. Pp. xiii+392. (Leipzig: W. Engelmann, 1910.) Price 7.40 marks.

THE author expounds a new interpretation of nature—a "Pythagorean-atomistic" evolution principle—which correlates a recognition of necessitarian uniformity with the concept of a high degree of contingency in natural happenings. The first part of the book is devoted to a historical sketch of the development of philosophic thought, in which the author discerns an analogy to the phyletic evolution of organisms. He then passes to a survey of the world of energies, and the discovery of its principle of development. The third section is devoted to the position of living organisms in nature, and here the author recognises that there is truth both in the vitalistic and in the mechanistic interpretations. But the mechanistic interpretations of vital activity that work are not like those which apply to the inorganic; there is a dualism and antagonism separating the two sets of formulæ. In fact, the organism stands by itself "with an independent genesis and tendency." In the fourth part of his book Dr. Strecker investigates the factors in the self-evolution of the animate world, and subjects "Darwinism" to a detailed criticism, his sympathies being Lamarckian. The chief point in the criticism is not unfamiliar, that selection is a secondary and directive, not a primary and originative factor. In the concluding part of this section there is an interesting discussion of "purposiveness," for instance, in development. This is regarded not as a fundamental property which explains things, but as a secondary achievement which has to be explained. It is not primary, but an outcome of progressive evolution. The concluding part of the book is on man's place in nature, and contains a vindication of an "anthropocentric" cosmology.

It may be of interest to give some further indication of the author's indictment of Darwinism. He criticises the concepts of the struggle for existence and natural selection, and shows that they tend to distract the attention from the primary fact and problem of the active organism, asserting itself in relation to the environment, and expressing itself ever in fresh form. In the second place, he seeks to show that some of the postulates are inconsistent with the actual facts of the case, and he raises difficulties, some of which have been very often discussed, regarding over-multiplication, the selection-value of a few additional millimetres on a primitive proboscidean's trunk, and the struggle among members of the same species. He utilises the facts of mutual aid as arguments against Darwinism, and in so doing shows, as it seems to us, a Procrustean conception of what the struggle for existence means.

Dr. Strecker leads his readers in an interesting way from the errors of Darwinism to the truth that is in Lamarck, and we are left at least with the impression that some compromise must be arrived at between the two interpretations. Not the least striking part of the book is the thesis that Darwinism is wrapped up with mechanistic, and Lamarckism with vitalistic views, and from this the author goes on to show that a recognition of the partial truth on either hand is to be found in his own particular theory of the "anthropocentric position" of man in the universe.

J. A. T.

RECENT PROGRESS OF SCIENCE.

Fortschritte der naturwissenschaftlichen Forschung. Edited by Prof. E. Abderhalden. Vol. i., pp. viii+306. Vol. ii., pp. iv+364. (Berlin and Vienna: Urban und Schwarzenberg, 1910–11.) Price, vol i., 10 marks; vol. ii., 12 marks.

THE plan of this new publication is to furnish summaries of recent results in selected departments of knowledge in which some degree of settlement and certainty has already been reached. This policy will avoid any risk of wasting time on raw speculations, and, under the able guidance of a man of Dr. Abderhalden's experience and prodigious industry, the series promises to be useful and judiciously chosen. In these first two volumes the subjects dealt with are colour photography (Miethe), fire-damp-resisting explosives (Brunswig), slow combustion and oxidation ferments (Bach), methods and recent results of gravitation measurements (Niethammer), development of picture telegraphy (Korn), recent methods of solar investigation (Guthnick), fermentation in living and "killed" plants (Palladin), origin of petroleum (Engler). Vol. ii.:—Inheritance of acquired characters (Semon), fossil lung-breathing aquatic animals (Stromer), volcanic research (Sapper), ions and electrons (Mie), utilisation of atmospheric nitrogen (Frenzel), cretinic degeneration, goitre, and deaf-mutism (Bircher), and muscular atrophy (Bing).

All these essays, written by men who have done some original work on the subjects dealt with (and sometimes a great deal of work), are well written, and occasionally only disappointing to the uninitiated on account of their caution. Thus Miethe regards a further sensational development of colour photography as very unlikely; Korn throws cold water on the problem of vision at a distance; and Sapper, after an exhaustive parade of recent volcanic theories (including Strutt's radio-activity speculations), calls for more facts. Some of the contributors are more positive. Brunswig confidently expects the discovery of a satisfactory explosive for coal-mines by judicious admixture of non-explosive material; Palladin considers the loss of coordination in the production of ferments after killing (by cold or narcotics) as definitely established; Semon commits himself to a modified Lamarckism on a basis of "mnemes" and "engrams"; and Bircher regards the influence of soil and water on cretinism as proven. Engler favours the view which ascribes the origin of petroleum to fossil animal fats.

The remaining articles are more or less neutral, but no less admirable, summaries of recent work. Mie's "Ions and Electrons" emphasises Maxwell's views of the æther rather more than we are accustomed to

find in Germany nowadays. It shows that the school which would regard the æther as a mere "physical space" has not yet captured all the Continental seats of learning. The further volumes are to appear at the rate of two per annum, and the list of forthcoming essays is distinctly attractive.

DISJUNCTIVE GEOGRAPHY.

A Systematic Geography of America. By G. W. Webb. Pp. viii+108. (London: Methuen and Co., Ltd., n.d.) Price 1s.

"THIS book—the fourth of a series of five—deals with the geography of the New World. As in the previous volumes, the treatment of the subject is on logical and modern lines, and the book will be found to contain the kind of information that candidates preparing for fairly advanced examinations in geography are now expected to acquire." Instances of the absence of modernity in the treatment are striking; for example, the rain of California is attributed to the north-east trades, without mention of its characteristic winter maximum, and in disregard of Buchan's maps on wind directions.

The space devoted to Argentina is the same as that given to Peru, and but one-quarter of that given to Canada. In view of the information which is accessible in the "Statesman's Year Book," the "Atlas of the World's Commerce," and the publications of the United States Government, the treatment of minerals in Mexico, the reference to cotton ports and to the trade of the United States ports on the Pacific, as well as the arbitrary division between the "wheat" and "maize" belts by lat. 42° N. are curious, and, on the whole, misleading. Mexico is first as to the production of silver, and produces copper, but not iron and tin to any extent.

Much is made of "Sea-island" cotton, but the total production of that variety is, roughly, 1/200th of the United States cotton crop, and stress is laid upon Mobile, Wilmington, Charleston, and Pensacola as cotton ports when really about three-quarters of the cotton exports go from Galveston, New Orleans, Savannah, and New York. On the Pacific coast Portland is suggested as of more importance than the ports on Puget Sound, when its trade is roughly only about one-third of that of the more northern ports. There seems hardly any excuse for the limitation of the "wheat" belt by latitude, especially as Wisconsin is named in large type, and the fact that in relation to area of land in the respective territories Pennsylvania is more important than Michigan is ignored.

On the whole the book contains many isolated facts, but surely modern ideas in geography demand a statement of facts in relation to each other; *e.g.* climate is discussed in an introductory chapter, and on the "wheat" belt the author writes:—"The winters in this region are very cold; the summers are warm, but not warm enough to ripen maize"; yet S. Dakota, Minnesota, Wisconsin, and Michigan produce annually over 200 million bushels of maize on the average. It appears that the defects are due to indiscriminate use of statements made in other text-books.

B. C. W.

OUR BOOK SHELF.

Laboratory Notes on Organic Chemistry for Medical Students. By Dr. Paul Haas. Pp. viii+128. (London: Macmillan and Co., Ltd., 1910.) Price 2s. 6d. net.

IT is generally recognised that a knowledge of organic chemistry is becoming more and more essential for the proper study of physiology and the medical sciences, but, on the other hand, the complaint is frequently heard that the curriculum of the medical student is becoming seriously overcrowded, and that science work is encroaching too far on the more professional studies.

The new syllabus of the second medical examination, part i., of the London University is the result of a compromise between these two points of view, and an attempt is being made to teach organic chemistry with special reference to its applications in physiology, pharmacology, and pathology, and while giving a sound elementary knowledge of the principles of the subject to illustrate them as far as possible by means of substances of importance in the aminol economy.

The book under review covers the practical syllabus of the above examination, and we may say at once that it is a good book, though it suffers from the defects inherent in any work written for so special a purpose. The first half of the book contains a lucid and thoughtful account of the general methods of organic chemistry, illustrative methods of preparation, and the various quantitative exercises mentioned in the syllabus. The second half is devoted to qualitative tests for a number of substances of physiological importance; and the practical recipes for preparing these substances, many of which are expensive and difficult to obtain in the market, will be found exceedingly useful, particularly by those teachers who may not be specially familiar with biochemical methods. A sufficient account of the theoretical principle underlying the various exercises and tests is given, and, where possible, the bearing of the subject on the future work of the student is emphasised, so that he may realise that chemistry is not to be regarded merely as an examination subject, but rather as a valuable adjunct to his knowledge for the fuller appreciation of his clinical and other studies. The book will, we think, be useful both to students and teachers.

Die Kalte: ihr Wesen, ihre Erzeugung und Verwertung. By Dr. H. Alt. Pp. v+124. (Leipzig: B. G. Teubner, 1910.) Price 1.25 marks.

THIS little book is based upon a series of six lectures delivered in München during 1907 by the author. Dr. Alt has endeavoured to popularise the subjects of the production of cold and the physics of low temperatures so as to render them both interesting and useful to the beginner. No special knowledge of this particular branch of physics is assumed; a general intelligence and interest in natural phenomena is all that is expected of the reader. With this in view the author devotes the first two chapters to matter which finds a place in almost any elementary treatise on heat. In the first chapter the properties and laws of gases are discussed, and in the second, those of vapours, both being obviously necessary preliminaries to the appreciation of the remaining sections of the book.

The production of cold by means of the reversed heat-engine, together with descriptions of the various types of refrigerator, form the subject of the next chapter; the remaining three are concerned with the question of the liquefaction of gases. The different processes by which liquefaction has been secured are described in chronological order, starting with the earlier regenerative process and leading up to the

methods by which hydrogen and helium have been liquefied by means of various improvements. Attention is directed in the concluding chapter to the many uses, both in the laboratory and commercially, to which low temperatures may be applied, such as the separation of the various ingredients of air by fractional distillation.

Most of the important points in connection with the production and applications of cold are to be found, treated in an elementary and lucid manner, in this book, which should serve admirably the purpose intended by its author.

Was die meisten Amateur- und manche Fachphotographen nicht wissen: Ein Handbuch praktischer Ratschläge und Erfahrungen. By Prof. F. Schmidt. Pp. xiii+175. (Leipzig: Verlag Otto Nemnich, 1911.)
